Carbohydrates, including sugar and starch, are widely distributed in plants and animals. They perform multiple functions, ranging from being structural components of deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) (*ribose* and *deoxyribose* sugars) to serving as sources of energy (*glucose*). Glucose is derived from the breakdown of carbohydrates in the diet (grains, starchy vegetables, and legumes) and in body stores (glycogen), and by endogenous synthesis from protein or the glycerol moiety of triglycerides. When energy intake exceeds expenditure, the excess is converted to fat and glycogen for storage in adipose tissue and liver or muscle, respectively. When energy expenditure exceeds calorie intake, endogenous glucose formation occurs from the breakdown of carbohydrate stores and from noncarbohydrate sources (e.g., amino acids, lactate, and glycerol).

The glucose concentration in the blood is maintained within a fairly narrow range under diverse conditions (feeding, fasting, or severe exercise) by hormones, such as insulin, glucagon, or epinephrine.

Measurement of glucose is one of the most commonly performed procedures in hospital chemistry laboratories. The most frequently encountered disorder of carbohydrate metabolism is high blood glucose caused by diabetes mellitus, which affects approximately 8% of the U.S. adult population. The incidence of hypoglycemia (low blood glucose) is unknown, but, excluding patients who use exogenous insulin to control blood glucose, it is low.

CHEMISTRY OF CARBOHYDRATES

Carbohydrates are aldehyde or ketone derivatives of polyhydroxy (more than one –OH group) alcohols, or compounds that yield these derivatives on hydrolysis. The term *carbohydrate* refers to hydrates of carbon and is derived from the observation that the empirical formulas for these compounds contain approximately one molecule of water per carbon atom. Thus glucose, $C_6H_{12}O_6$, and lactose, $C_{12}H_{22}O_{11}$, can be written as $C_6(H_2O)_6$ and $C_{12}(H_2O)_{11}$, respectively. These compounds are not hydrates in the usual chemical sense, however, and noncarbohydrate compounds, such as lactic acid, $CH_3CH(OH)COOH$ or $C_3(H_2O)_3$, can have similar empirical formulas.

MONOSACCHARIDES

Monosaccharides, or simple sugars, consist of a single polyhydroxy aldehyde or ketone unit and cannot be hydrolyzed to a simpler form. The backbone is made up of a number of carbon atoms. Sugars containing three, four, five, six, and seven carbon atoms are known as *trioses, tetroses, pentoses, hexoses,* and *heptoses,* respectively. One of the carbon atoms is double bonded to an oxygen atom to form a carbonyl group. An *aldehyde* has the carbonyl group at the end of the carbon chain, whereas if the carbonyl group is at any other position, a *ketone* is formed (Figure 25-1). The simplest carbohydrate is glycol aldehyde, the aldehyde derivative of ethylene glycol. The aldehyde and ketone derivatives of glycerol are, respectively, glyceraldehyde and dihydroxyacetone (see Figure 25-1). Monosaccharides are termed *aldose* or *ketose,* according to the position of the carbonyl group (Figure 25-2).

Compounds that are identical in composition and differ only in spatial configuration are called *stereoisomers.* The carbon atoms in the unbranched chain are numbered, as shown by the numbers at the left of the formula for D-glucose (see Figure 25-2). The designation D or L refers to the position of the hydroxyl group on the carbon atom adjacent to the last (bottom) CH_2OH group. In general, the designation of D and L *for a sugar molecule refers to the stereoisomeric forms of the highest-numbered asymmetrical*

*The author gratefully acknowledges the original contributions by Drs. Wendell T. Caraway and Nelson B. Watts on which portions of this chapter are based.

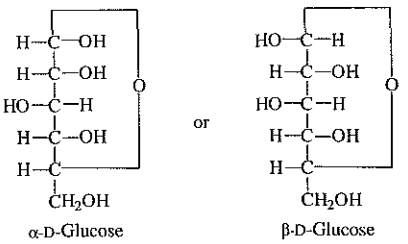

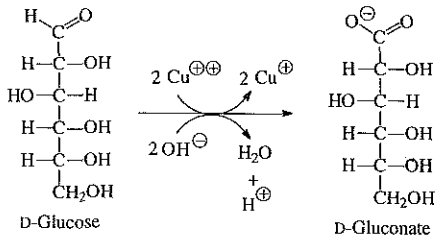

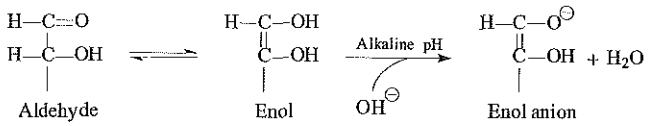

Figure 25-3 Structure of D-glucose (hemiacetal form).

*carbon atom.** By convention, the D-sugars are written with the hydroxyl group on the right and the L-sugars are written with the hydroxyl group on the left (see Figure 25-2). *Most sugars in the human body are of the D-configuration.* A number of different structures exist, depending on the relative positions of the hydroxyl groups on the carbon atoms.

The formula for glucose can be written in the form of either aldehyde or enol, a short-lived reactive species. Shift to the enol anion is favored in alkaline solution:

The presence of a double bond and a negative charge in the enol anion makes glucose an active reducing substance that can be oxidized by relatively mild oxidizing agents, such as cupric (Cu^{2+}) and ferric (Fe^{3+}) ions. Glucose in hot alkaline solution readily reduces cupric ions to cuprous ions, and the carbonyl carbon is oxidized to carboxylic acid. The color change can be used as a presumptive indication for the presence of glucose, and for many years blood and urine glucose were measured this way. Other sugars can reduce cupric ions in alkaline solution.

Aldehyde and alcohol groups can react to form hemiacetals. In the case of glucose, the aldehyde group reacts with the hydroxyl group on carbon 5 (Figure 25-3). Note that this ring structure contains an additional asymmetric carbon atom and can exist in two stereoisomeric forms. By convention, the form with the hydroxyl group on the right of the first carbon atom is called α-D-*glucose* and the form with the hydroxyl group on the left is called β-D-*glucose.* The common anhydrous crystalline glucose is in the α-D-form. The β-D-form is obtained by crystallization from acetic acid. The two forms differ with respect to optical rotation of polarized light. The specific rotation—$[\alpha]_D^{25}$—for the α-D-form is +113° and for the β-D-form is +19.7°. As a result of mutarotation, either form in aqueous solution gives rise to an equilibrium mixture that has a specific rotation of +52.5°. The equilibrium established at room temperature is such that about 36% of the glucose exists in the α-form and 64% in the β-form; only a trace remains in the free aldehyde form. The enzyme glucose oxidase reacts only with β-D-glucose. For this reason, calibrating solutions to be used in glucose oxidase methods for glucose determinations should be permitted to stand at least 2 hours to obtain equilibrium comparable with that in the test samples to be analyzed.

From the ring structures shown in Figure 25-3, it is not apparent why the aldehyde group should react with the distant hydroxyl group on carbon 5. The spatial arrangement of the atoms is better represented by a symmetrical ring structure, depicted by the Haworth formula, in which glucose is considered as having the same basic structure as pyran (Figure 25-4). In this formula, the plane of the ring is considered to be perpendicular to the plane of the paper, with the heavy lines pointing toward the reader. *Hydroxyl groups in position 1 are then below the plane (α-configuration)* or *above the plane (β-configuration).* A six-member ring sugar, containing five carbons and one oxygen, is a deriva-

*Although the D and L designations are retained in this chapter, readers should be aware that in the Cahn-Ingold-Prelog system, a series of sequence rules determines configurations. In this new system, the symbols R and S are used to designate configurations instead of D and L. For further information, readers are referred to March J. Advances in organic chemistry: Reactions, mechanisms, and structure, 4th ed. New York: John Wiley & Sons, 1992: 109-111.

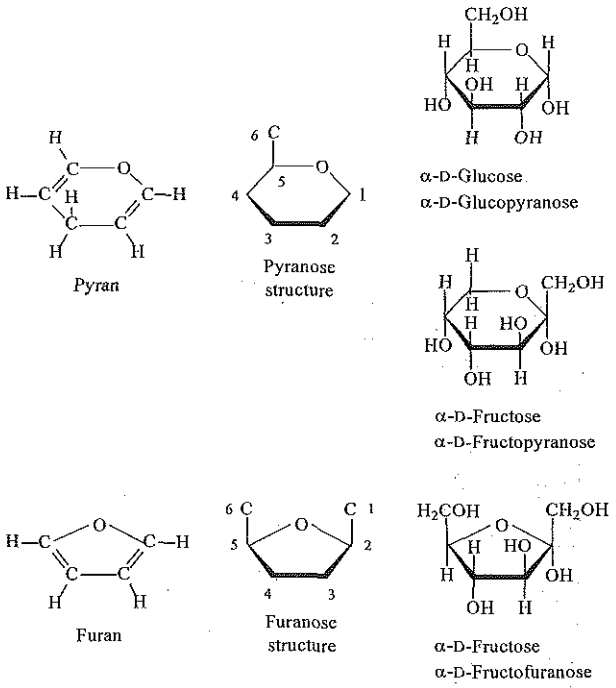

Figure 25-4 The Haworth formula for sugars.

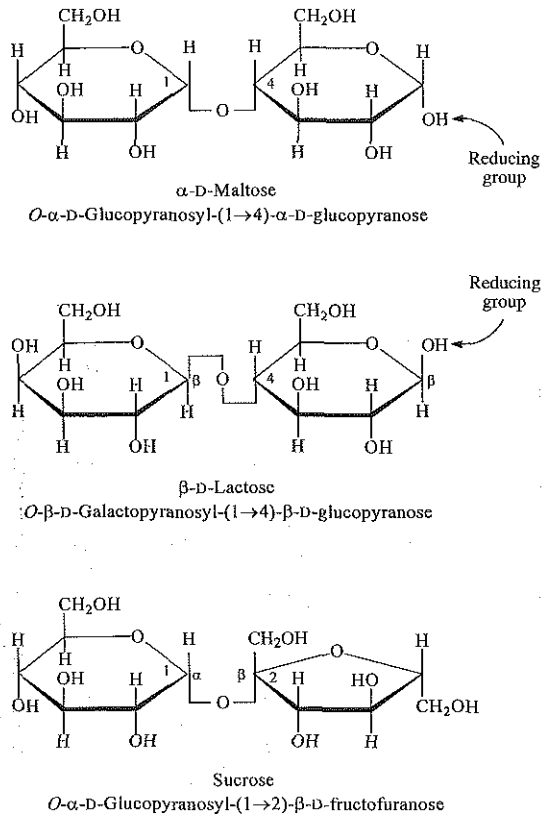

Figure 25-5 Structural formulas of disaccharides.

tive of pyran and is called a *pyranose.* When linkage occurs with formation of a five-member ring, containing four carbons and one oxygen, the sugar has the same basic structure as furan and is called a *furanose.* Representative formulas are shown in Figure 25-4. Fructose is shown in two cyclical forms. Fructopyranose is the configuration of the free sugar, and fructofuranose occurs whenever fructose exists in combination in disaccharides and polysaccharides, as in sucrose and inulin.

Disaccharides

Two monosaccharides join covalently by an *O-glycosidic bond,* with the loss of a molecule of water, to form a disaccharide. The chemical bond between the sugars always involves the aldehyde or ketone group of one monosaccharide joined to an alcohol group (e.g., maltose) or to an aldehyde or ketone group (e.g., sucrose) of the other monosaccharide. The most common disaccharides are

Maltose = glucose + glucose
Lactose = glucose + galactose
Sucrose = glucose + fructose

There are several conventions that are followed in the nomenclature of disaccharides (Figure 25-5). The compound is written with the nonreducing end to the left. An *O* precedes the name of the first (left) monosaccharide, emphasizing that the linkage occurs by an oxygen atom. The configuration of the anomeric (carbonyl) carbon is designated α or β. Five- (furanosyl) and six- (pyranosyl) membered rings are distinguished and the carbon atoms joined by the glycosidic bond are identified. Because sucrose has no reducing end, it can be written as *O*-α-D-glucopyranosyl-(1 → 2)-β-D-fructofuranose or *O*-β-D-fructofuranosyl-(2 → 1)-α-D-glucopyranose. If the linkage between two monosaccharides is between the aldehyde or ketone group of one molecule and a hydroxyl group of another molecule (as in maltose and lactose), one potentially free ketone or aldehyde group remains on the second monosaccharide. Consequently, the second glucose residue can be oxidized (thus the disaccharide is a reducing sugar) and is capable of existing in α- or β-pyranose forms. The reducing power, however, is only approximately 40% of the reducing power of the two single monosaccharides added together, primarily because one of the reducing groups is not available. On the other hand, if the linkage between two monosaccharides involves the aldehyde or ketone groups of both molecules (as in sucrose), a nonreducing sugar results because no free aldehyde or ketone group remains.

Polysaccharides

The linkage of multiple monosaccharide units results in the formation of polysaccharides. The major storage carbohydrates are *starch* in plants and *glycogen* in animals, both of which form granules inside cells. The suffix *an* attached to a name of a monosaccharide indicates the main type of sugar present in the polysaccharide. Starch and glycogen, for example, are *glucosans,* because they are composed of a series of glucose molecules. Inulin, a polysaccharide found in the tubers of certain plants, consists largely of fructose units and is known as a *fructosan.*

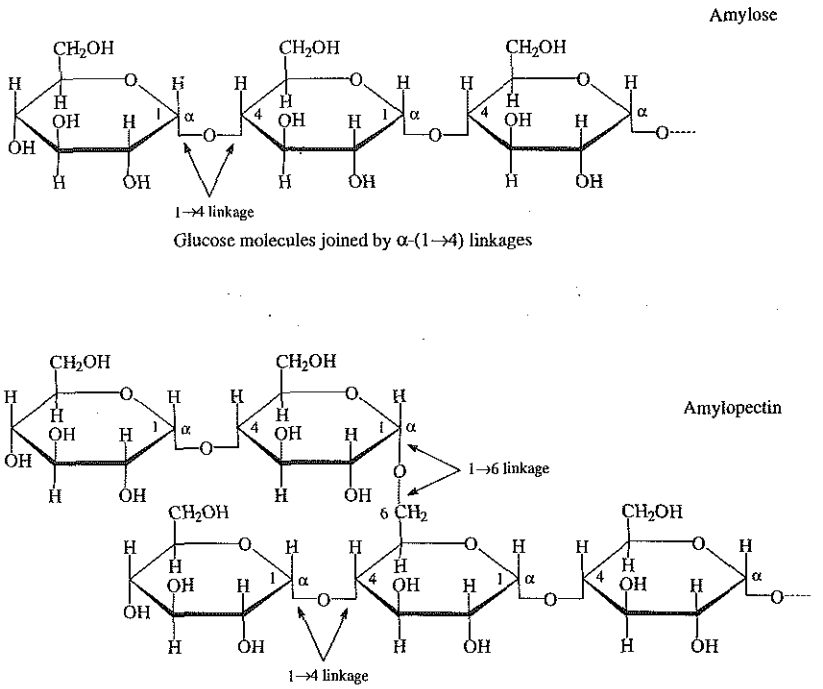

Figure 25-6 Structures of the polysaccharides amylose and amylopectin.

Nearly all starches consist of a mixture of two kinds of glucosans called *amyloses* and *amylopectins.* The relative proportions of these two glucosans in a starch vary from approximately 20% amylose and 80% amylopectin in wheat, potato, and ordinary corn starch to nearly 100% amylopectin in the starch of waxy corn. On the other hand, a few corn starches are known to contain as much as 75% amylose. Both amylose and amylopectin consist of glucose residues, but their structures exhibit one significant difference. Amylose consists of one long unbranched chain of glucose units linked together by α-1,4-linkages with only the terminal aldehyde group free (Figure 25-6). In amylopectin, most of the units are similarly connected with α-1,4-links, but there are also α-1,6-glycosidic bonds every 24 to 30 residues, producing side chains (see Figure 25-6). Amylopectin contains up to 1 million glucose residues. The structure of glycogen is similar to that of amylopectin, but branching is more extensive in glycogen and occurs every 8 to 12 glucose residues. These branches enhance the solubility of glycogen and allow the glucose residues to be mobilized more readily. Glycogen is most abundant in liver and also is found in skeletal muscle. The most favorable conformation for α-1,4-linked polymers of D-glucose, such as starch or glycogen, is a tightly coiled helical structure.

The difference in structure between amylose and amylopectin is important when selecting the appropriate starch substrate for amylase determinations (see Chapter 21). The rate of hydrolysis is affected by structural differences in the starch. α-Amylase from the pancreas hydrolyzes internal α-1,4-glycosidic linkages. This hydrolysis results initially in the production of some maltose and a mixture of dextrins, which are subsequently hydrolyzed to maltose. The β-1,6-linkages are not attacked by α-amylase, and relatively large molecules of so-called residual (limit) dextrins are left after the action of the enzyme on amylopectin. Iodine gives a deep blue color with amylose and a red to violet color with amylopectin. These characteristic colors disappear when the respective glucosans are hydrolyzed to smaller units, such as dextrins and maltose. This disappearance of the starch-iodine color is used in some older methods for amylase determination.

Dextrins are the products of partial hydrolysis of starch. They are a complex mixture of molecules of different sizes. Those formed from amylose are unbranched chains, whereas amylopectins produce branched chains of glucose molecules. Erythrodextrins are larger branched dextrins that turn a reddish color on complexing iodine.

Cellulose, an important structural polysaccharide in plants, is an unbranched polymer of glucose residues joined by β-1,4-linkages. The β-configuration facilitates the formation of long straight chains, producing fibers of high tensile strength. The β-1,4-linkages are not hydrolyzed by α-amylases. Because humans do not have *cellulases,* they are unable to digest vegetable fiber.

Chitin, the principal component of the exoskeleton of arthropods (insects and crustacea), consists of *N*-acetyl-D-glucosamine residues in a β-1,4-linkage. The only chemical difference from cellulose is that the substituent at C-2 is an acetylated amino group instead of a hydroxyl group.

GLYCOPROTEINS

Glycosylation is the most frequent enzymatic modification of proteins. Many integral membrane proteins have oligosaccharides covalently attached to the extracellular region,

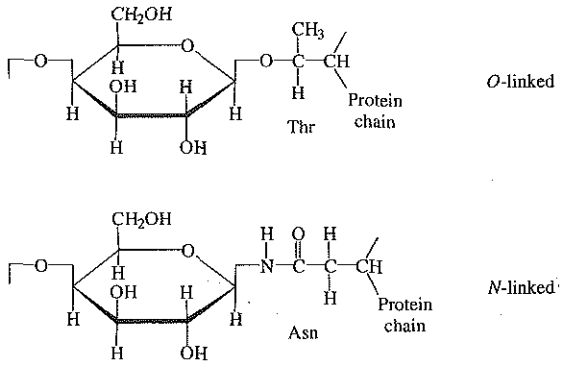

Figure 25-7 Glycosidic linkages between oligosaccharides and protein.

forming *glycoproteins.* In addition, most proteins that are secreted, such as antibodies, hormones, and coagulation factors, are glycoproteins. The number of attached carbohydrates varies among proteins and constitutes 1% to 70% of the weight of the glycoprotein. The oligosaccharides are attached either by *O*-glycosidic linkages to the side-chain oxygen of serine and/or threonine residues or by *N*-glycosidic linkages to the side-chain nitrogen of asparagine residues (Figure 25-7).

One of the biological functions of the carbohydrate chains is to regulate the lifespan of proteins. For example, removal of sialic acid residues from the end of oligosaccharide chains on erythrocytes results in the disappearance of the red blood cells from the circulation. Carbohydrates have also been implicated in cell-cell recognition, and in secretion and targeting of proteins to specific subcellular domains. Recently, defects in protein glycosylation have been linked to several forms of congenital muscular dystrophy that are associated with brain abnormalities.[183]

METABOLISM OF CARBOHYDRATES

Carbohydrate metabolism provides glucose, the primary energy source for the human body. After digestion of carbohydrates and absorption of glucose, blood glucose concentration is controlled by the action of several hormones. Glucose can be synthesized de novo or stored in the tissue as glycogen.

Digestion and Absorption

Ingested starch and glycogen are partially digested by the action of salivary amylase in the mouth to form intermediate dextrins and maltose (see also Chapter 48). The acid pH of the stomach inhibits amylase activity, but the alkaline pancreatic secretions increase the pH in the small intestine, allowing pancreatic amylase to complete digestion to oligosaccharides, preponderantly maltose. Maltose, along with any ingested lactose and sucrose, is hydrolyzed by the appropriate disaccharidase (*maltase, lactase,* or *sucrase*) from the intestinal mucosa to glucose, galactose, and fructose.

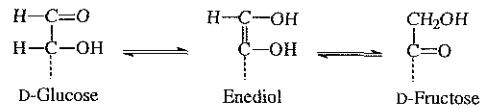

Figure 25-8 Interconversion of glucose and fructose.

These monosaccharides are absorbed across the wall of the duodenum and ileum by an active, energy-requiring, carrier-mediated transfer process. The rate of absorption for glucose and galactose is several times greater than for similar molecules absorbed by passive diffusion (e.g., xylose). Some conversion of fructose to glucose may occur during the process of absorption, and the interconversion can be visualized in terms of the enediol form common to both (Figure 25-8). Fructose is absorbed more slowly than glucose and galactose by a carrier-mediated process different from the glucose and galactose transport mechanisms. The monosaccharides are then transported by the portal vein to the liver.

Intermediary Metabolism

The metabolism of hexoses proceeds according to the body's requirements. This results in (1) energy production by conversion to carbon dioxide and water, (2) storage as glycogen in the liver or triglyceride in adipose tissue, or (3) conversion to keto acids, amino acids, or protein.

Some steps in the intermediary metabolism of glycogen and hexoses are shown in Figure 25-9. Each step is enzymatically catalyzed. In some cases, different enzymes are responsible for the forward and reverse reactions. For example, the initial phosphorylation of glucose is mediated by glucokinase, but the reverse reaction depends on glucose-6-phosphatase.

Various inborn errors of metabolism (Table 25-1) result from deficiencies or absence of some of the enzymes listed in Figure 25-9. Some of these are discussed later in the chapter. The relationship of carbohydrate metabolism to the production of lactate, ketone bodies, and triglycerides is also depicted in Figure 25-9. The pentose phosphate pathway, also known as the *hexose monophosphate shunt,* is an alternative pathway for glucose metabolism that generates the reduced form of nicotinamide-adenine dinucleotide phosphate (NADPH), which is used in maintaining the integrity of red blood cell membranes, in lipid and steroid biosynthesis, in hydroxylation reactions, and in other anabolic reactions. The complete picture of intermediary metabolism of carbohydrates is rather complex and interwoven with the metabolism of lipids and amino acids. For details, readers should consult a biochemistry textbook.

Regulation of Blood Glucose Concentration

The concentration of glucose in the blood is regulated by a complex interplay of multiple pathways, modulated by a number of hormones. *Glycogenesis* is the conversion of glucose to glycogen. The reverse process, namely the break-

down of glycogen to glucose and other intermediate products, is termed *glycogenolysis.* The formation of glucose from noncarbohydrate sources, such as amino acids, glycerol, or lactate, is termed *gluconeogenesis.* The conversion of glucose or other hexoses into lactate or pyruvate is called *glycolysis.* Further oxidation to carbon dioxide and water occurs through the Krebs (citric acid) cycle and the mitochondrial electron transport chain coupled to oxidative phosphorylation, generating energy in the form of adenosine triphosphate (ATP). Oxidation of glucose to carbon dioxide and water also occurs through the hexose monophosphate shunt pathway, which produces NADPH.

Hormones That Regulate Blood Glucose Concentration

During a brief fast, a precipitous decline in the concentration of blood glucose is prevented by breakdown of glycogen stored in the liver and synthesis of glucose in the liver. Some glucose is derived from gluconeogenesis in the kidneys.[100] These organs contain glucose-6-phosphatase, which is necessary to convert glucose-6-phosphate (derived from either gluconeogenesis or glycogenolysis) to glucose. Skeletal muscle lacks this enzyme, and muscle glycogen therefore cannot contribute directly to blood glucose. With more prolonged fasting (longer than 42 hours), gluconeogenesis accounts for essentially all of the glucose production. In contrast, after a meal, the absorbed glucose is converted to glycogen (for storage in the liver and skeletal muscle) or fat (for storage in adipose tissue). Despite large fluctuations in the supply and demand of carbohydrates, the concentration of glucose in the blood is normally maintained within a narrow range by hormones that modulate the movement of glucose into and out of the circulation. These include insulin, which decreases blood glucose, and the counterregulatory hormones (glucagon, epinephrine, cortisol, and growth hormone), which increase blood glucose concentrations (Figure 25-10).[100] Normal glucose disposal depends on: (1) the ability of the pancreas to secrete insulin, (2) the ability of insulin to promote uptake of glucose into peripheral tissue, and (3) the ability of insulin to suppress hepatic glucose production. The major insulin target organs are liver, skeletal muscle, and adipose tissue. These organs exhibit some differences in their responses to insulin. For example, the hormone stimulates glucose uptake through a specific glucose transporter—GLUT4—in muscle and fat cells, but not liver cells.

Insulin

Insulin is a protein hormone produced by the β-cells of the islets of Langerhans in the pancreas. Insulin was the first protein hormone to be sequenced, the first substance to be measured by radioimmunoassay (RIA), and the first compound produced by recombinant DNA technology for practical use. It is an anabolic hormone that stimulates the uptake of glucose into fat and muscle, promotes the conversion of glucose to glycogen or fat for storage, inhibits glucose production by the liver, stimulates protein synthesis, and inhibits protein breakdown.

Chemistry. Human insulin (MW 5808) consists of 51 amino acids in two chains (A and B) joined by two disulfide bridges, with a third disulfide bridge within the A chain. The amino acid sequence of human insulin differs slightly from insulin of other species, but the carboxyl terminal region of the B chain (B23 to B26), which appears crucial for the biological actions of insulin, is highly conserved among species. Insulin from most animals is immunologically and biologically similar to human insulin, and in the past patients were treated with insulin purified from beef or pig pancreas. The most commonly used forms now are recombinant human insulins.

Synthesis. Preproinsulin, a protein of about 100 amino acids (MW 12,000), is formed by ribosomes in the rough endoplasmic reticulum of the pancreatic β-cells (Figure 25-

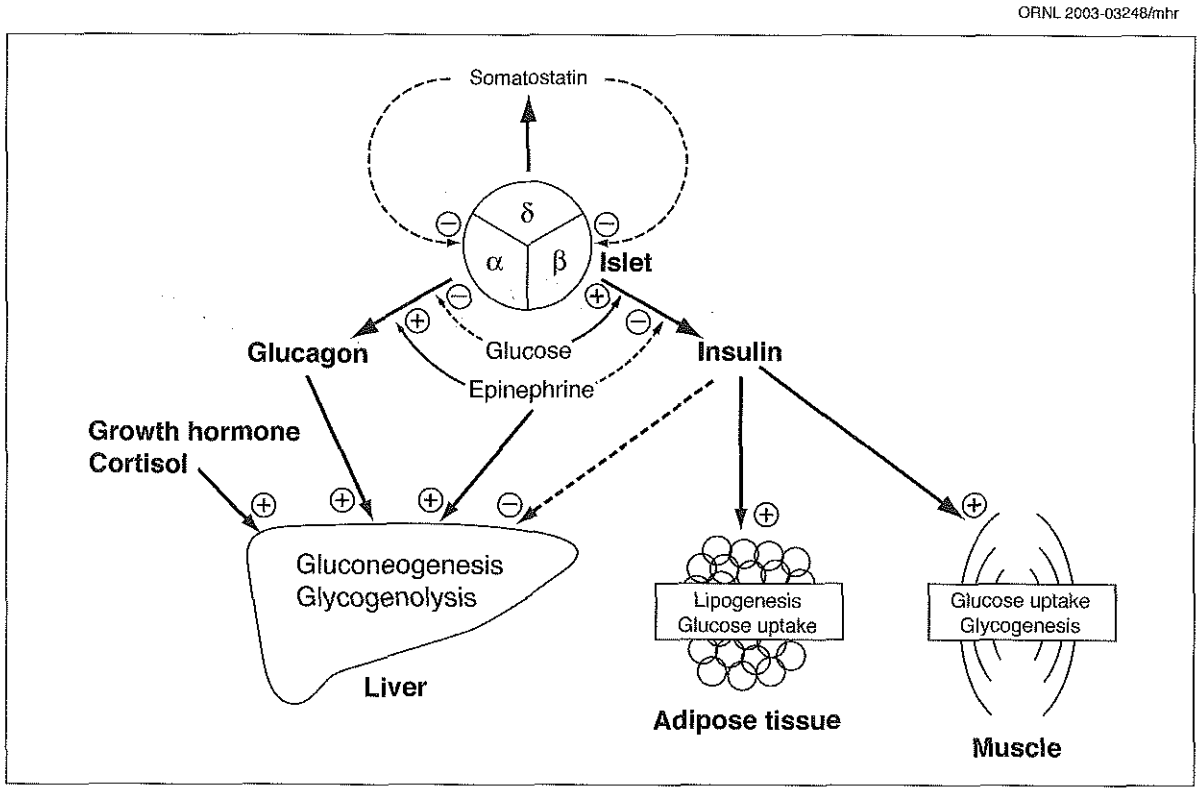

Figure 25-10 Hormonal regulation of blood glucose. Key: +, stimulation; –, inhibition. Cortisol, growth hormone, and epinephrine also antagonize the effect of insulin.

11). Preproinsulin is not detectable in the circulation under normal conditions because it is rapidly converted by cleaving enzymes to proinsulin (MW 9000), an 86–amino acid polypeptide. This is stored in secretory granules in the Golgi complex of the β-cells, where *proteolytic cleavage to insulin and connecting peptide (C-peptide) occurs.*[210] Cleavage of proinsulin is catalyzed by two Ca^{2+}-regulated endopeptidases, prohormone convertases 1 and 2 (PC1 and PC2).[232] PC1 (sometimes designated PC3) hydrolyzes the molecule on the C-terminal end of Arg-31 and Arg-32 (at the BC junction) to yield split 32, 33 proinsulin (Figure 25-12). PC2 cleaves proinsulin on the C-terminal side of dibasic residues Lys-64 and Arg-65 (at the AC junction) to generate split 65, 66 proinsulin. Each enzymatic hydrolysis is rapidly followed by the removal of two newly exposed C-terminal basic amino acids by carboxypeptidase-H to produce insulin and C-peptide. The split proinsulin intermediates are rarely detected in patient samples because of the relatively high quantity of carboxypeptidase-H. This enzyme produces the more commonly observed proinsulin intermediates, des 31, 32 proinsulin and des 64, 65 proinsulin (see Figure 25-12). Most proinsulin processing is sequential. Intact proinsulin is initially hydrolyzed by PC1 and carboxypeptidase-H. The resultant des 31, 32 proinsulin is converted by PC2 and carboxypeptidase-H to insulin and C-peptide. Less than 10% of proinsulin is metabolized via des 64, 65 proinsulin, which is present in negligible amounts in humans. Des 31, 32 proinsulin is the major proinsulin conversion intermediate.[260] Glucose regulates biosynthesis of both proinsulin and PC1, but has no effect on PC2 and carboxypeptidase-H. At the cell membrane, insulin and C-peptide are released into the portal circulation in equimolar amounts. In addition, small amounts of proinsulin and intermediate cleavage forms enter the circulation.

Release. Glucose, amino acids, pancreatic and gastrointestinal hormones (e.g., glucagon, gastrin, secretin, pancreozymin, and gastrointestinal polypeptide), and some medications (e.g., sulfonylureas and β-adrenergic agonists) stimulate insulin secretion. Insulin release is inhibited by hypoglycemia, somatostatin (produced in the pancreatic δ-cells), and various drugs (e.g., α-adrenergic agonists, β-adrenergic blockers, diazoxide, phenytoin, phenothiazines, and nicotinic acid).[219] In healthy individuals, insulin is secreted in a pulsatile fashion, with glucose and insulin the main signals in the feedback loop. Glucose elicits the release of insulin from the pancreas in two phases. The first phase begins 1 to 2 minutes after intravenous injection of glucose and ends within 10 minutes. This phase, illustrated by the sharp spike in Figure 25-13, *A*, represents the rapid release of stored insulin. The second phase, beginning at the point where the first phase ends, depends on continuing insulin synthesis and release and lasts until normoglycemia has been restored, usually within 60 to 120 minutes. With progressive failure of β-cell function, the first-phase insulin response to

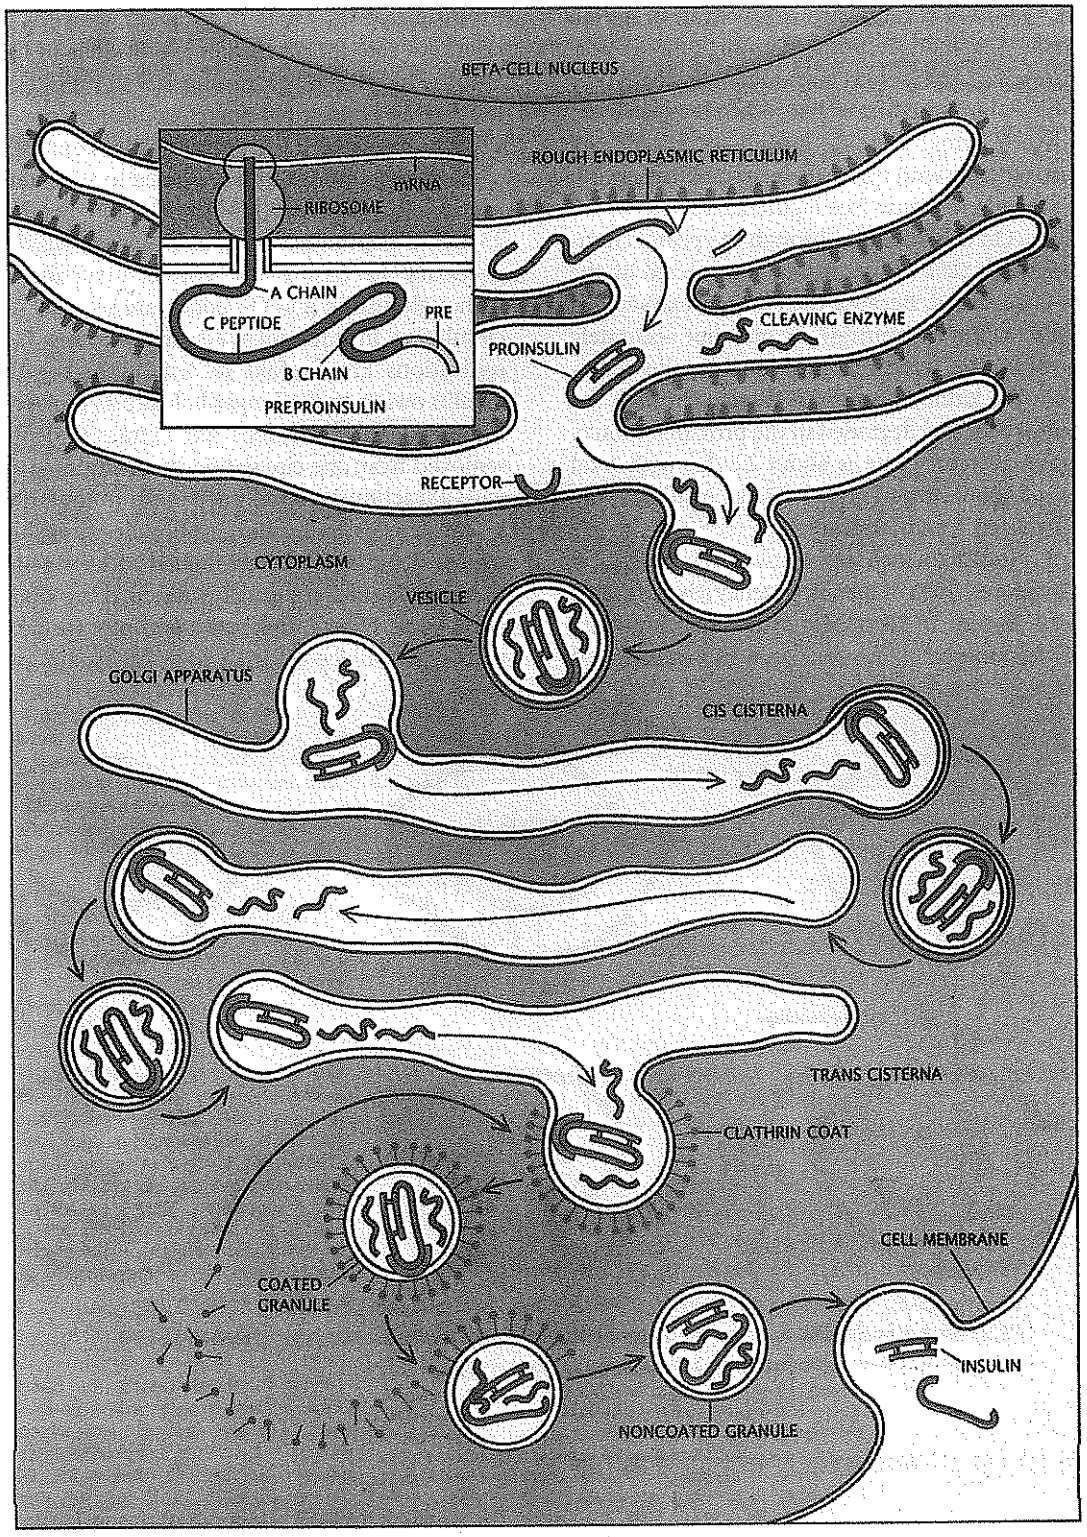

Figure 25-11 Insulin synthesis and release from the pancreatic β-cell. *(From Orci L, Vassalli J-D, Perrelet A. The insulin factory. Sci Am 1988; 259:85-94.)*

glucose is lost, but other stimuli such as glucagon or amino acids may be able to elicit this response. Although the second-phase insulin response is preserved in most patients with type 2 diabetes mellitus, both the first-phase response (see Figure 25-13, *B*) and the normal pulsatile insulin secretion[209] are lost. In contrast, patients with type 1 diabetes mellitus exhibit minimal or no insulin response (see Figure 25-13, *C*).

Degradation. On the first pass through the portal circulation, approximately 50% of the insulin is extracted by the liver, where it is degraded. Because the amount extracted is variable, plasma insulin concentrations may not accurately reflect the rate of insulin secretion. Additional insulin degradation occurs in the kidneys. Insulin is filtered through the glomeruli, reabsorbed, and degraded in the proximal tubule. The basal insulin secretory rate is about 1 U/hr, with total daily secretion of about 40 U. The half-life of insulin in the circulation is between 4 and 5 minutes.

Proinsulin. Proinsulin, which has relatively low biological activity (approximately 10% of insulin potency), is the major storage form of insulin.[236] Normally, only small amounts (about 3% of the amount of insulin, on a molar basis) of proinsulin enter the circulation. However, the hepatic clearance rate for proinsulin is only 25% of that for insulin and the half-life of proinsulin is ~30 minutes. Therefore in the fasting state, circulating proinsulin concentrations are approximately 10% to 15% of insulin concentrations.

C-Peptide. Proinsulin is cleaved to a 31–amino acid connecting (C) peptide (MW 3600) and insulin (see Figure 25-12). C-peptide is devoid of biological activity but appears necessary to ensure the correct structure of insulin.[122] Although insulin and C-peptide are secreted into the portal circulation in equimolar amounts, fasting C-peptide concentrations are fivefold to tenfold higher than those of insulin owing to the longer half-life of C-peptide (about 35 minutes). The liver does not extract C-peptide, which is removed from the circulation by the kidneys and degraded, with a fraction excreted unchanged in the urine.

Antibodies to Insulin. Antibodies to insulin develop in almost all patients who are treated with exogenous insulin.[235] These antibodies are usually present at low titer and produce no adverse effects. On rare occasions (usually in patients with type 2 diabetes) high titers of insulin antibodies may

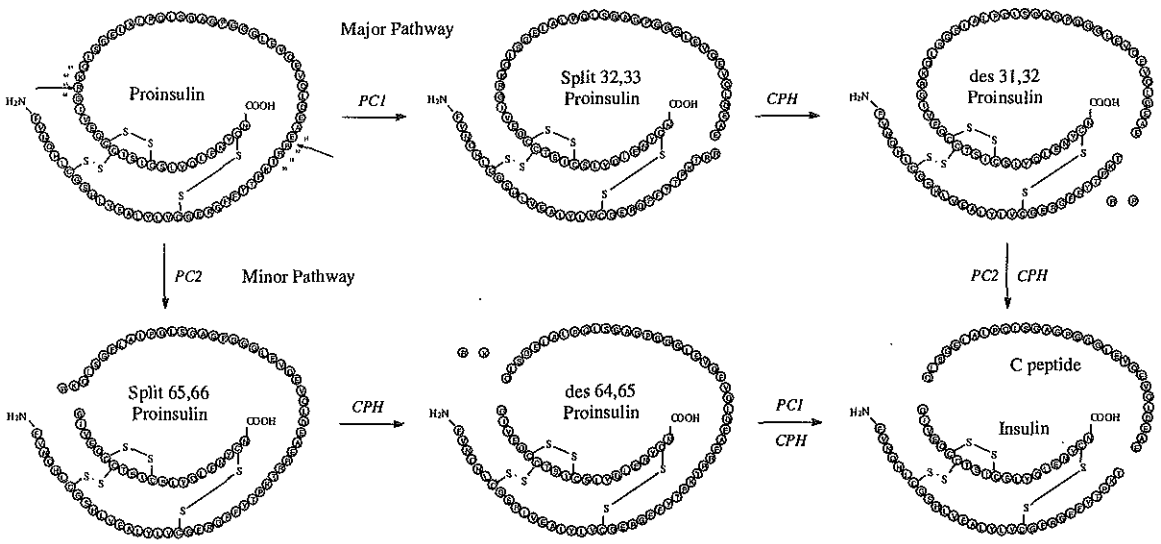

Figure 25-12 Processing of proinsulin. The enzymes prohormone convertase 1 and 2 (PC1 and PC2) act on proinsulin to form the appropriate split proinsulins. Carboxypeptidase-H (CPH) removes the two exposed basic amino acid residues *(circles)*.

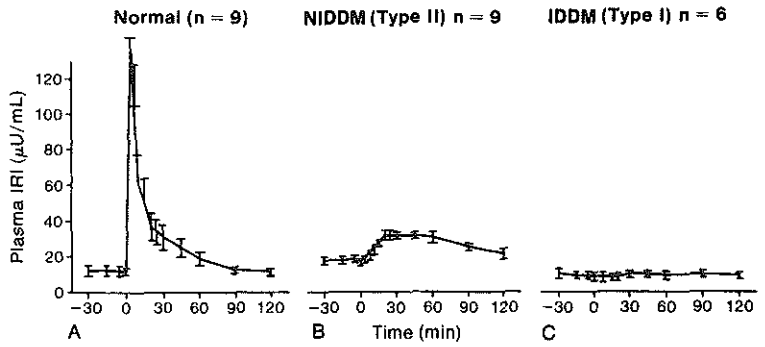

Figure 25-13 Response of plasma insulin to glucose stimulation. cause insulin resistance. Improvement in the purity of animal insulins and the widespread use of human insulin have reduced, but not eliminated, antibody production. Antibodies to insulin rarely develop in patients who have not received exogenous insulin.

Although rare, patients with antibodies to the insulin receptor have also been described.[91] On binding the receptor, these antibodies act as either antagonists, producing hyperglycemia (e.g., in patients with acanthosis nigricans), or agonists, resulting in hypoglycemia.

The Mechanism of Insulin Action. Although the metabolic effects produced by insulin are well known, the molecular mechanism of insulin action remains incompletely understood.[233,244] It is generally accepted that the initial event is the binding of insulin to specific receptors in the plasma membrane (Figure 25-14). The human insulin receptor, which is well characterized, is a heterotetramer, comprising two α- and two β-subunits. The α-subunit (MW 135,000) is located on the outer surface of the plasma membrane and contains the site where insulin binds. The β-subunit (MW 95,000) extends intracellularly through the plasma membrane and contains an intrinsic tyrosine kinase. Binding of insulin to the α-subunits induces a conformational change in the receptor, resulting in activation of the tyrosine kinase that catalyzes the phosphorylation of tyrosine residues on several proteins. One of the major substrates for this tyrosine kinase is the receptor itself.

In addition to phosphorylating itself, the insulin receptor catalyzes the tyrosine phosphorylation of a number of specific intracellular proteins (see Figure 25-14). These include the four members of the family of insulin-receptor substrate (IRS) proteins (termed IRS-1, IRS-2, IRS-3, and IRS-4), Shc, and Gab-1. The phosphorylated tyrosines on these target proteins act as docking sites for selected intracellular signal transducer proteins.[290] Most of these transducer proteins contain one or more Src homology 2 (SH2) domains. The SH2 domain is a sequence of approximately 100 amino acids that recognizes phosphotyrosine.[218] Sequence differences in the SH2 domain dictate the specificity of binding. SH2-containing proteins depicted in Figure 25-14 include those labeled phosphatidylinositol 3′-kinase (PI3K) and growth factor receptor-bound protein 2 (Grb2), which mediate downstream signal transduction events. Like other growth factors, insulin stimulates the mitogen-activated protein (MAP) kinase cascade via ras. In addition, phosphatidylinositol 3′-kinase activates atypical protein kinase C (aPKC) via Akt. The latter enzymes regulate glucose transport by modulating translocation of GLUT4 (the insulin-sensitive glucose transporter) to the plasma membrane. Akt also phosphorylates and inactivates GSK-3, thereby enhancing glycogen synthesis. Some of these events are listed in Figure 25-14. The pathways are elaborate, and although several components have been identified, there remain considerable gaps in our knowledge and understanding. Recent studies have clarified a fundamental concept, that the insulin-mediated signaling events are highly redundant. For example, when two key insulin-signaling molecules, IRS-1 and GLUT4, were knocked out in transgenic mouse experiments, the resulting animals had minor metabolic defects rather than overt diabetes.[233] Similarly, mice with knockout of insulin receptors from skeletal muscle or liver do not develop diabetes.

Glucose Transport. The transport of glucose into cells is modulated by two families of proteins.[29] The intestinal sodium/glucose co-transporter promotes the uptake of glucose and galactose from the lumen of the small bowel and their reabsorption from the urine in the kidney. The transporter uses the electrochemical sodium gradient to transport glucose against its concentration gradient. Members of the second family of glucose carriers are called *facilitative glucose transporters* (GLUT) (Table 25-2). These transporters are designated GLUT1 to GLUT7, based on the order in which they were identified. GLUT1 is widely expressed and provides many cells with their basal glucose requirement.

TABLE 25-2 Facilitative Human Glucose Transporters

Name	Tissue	Function
GLUT1 (erythrocyte)	Wide distribution, especially brain, kidney, colon, and fetal tissues	Basal glucose transport
GLUT2 (liver)	Liver, β-cells of pancreas, small intestine, and kidney	Non–rate-limiting glucose transport
GLUT3 (brain)	Wide distribution, especially neurons, placenta, and testis	Glucose transport in neurons
GLUT4 (muscle)	Skeletal muscle, cardiac muscle, and adipose tissue	Insulin-stimulated glucose transport
GLUT5 (small intestine)	Small intestine, kidney, skeletal muscle, brain, and adipose tissue	Transports fructose (not glucose)
GLUT6	—	Pseudogene that is nonfunctional
GLUT7 (microsomal)	Liver	Release of glucose from endoplasmic reticulum

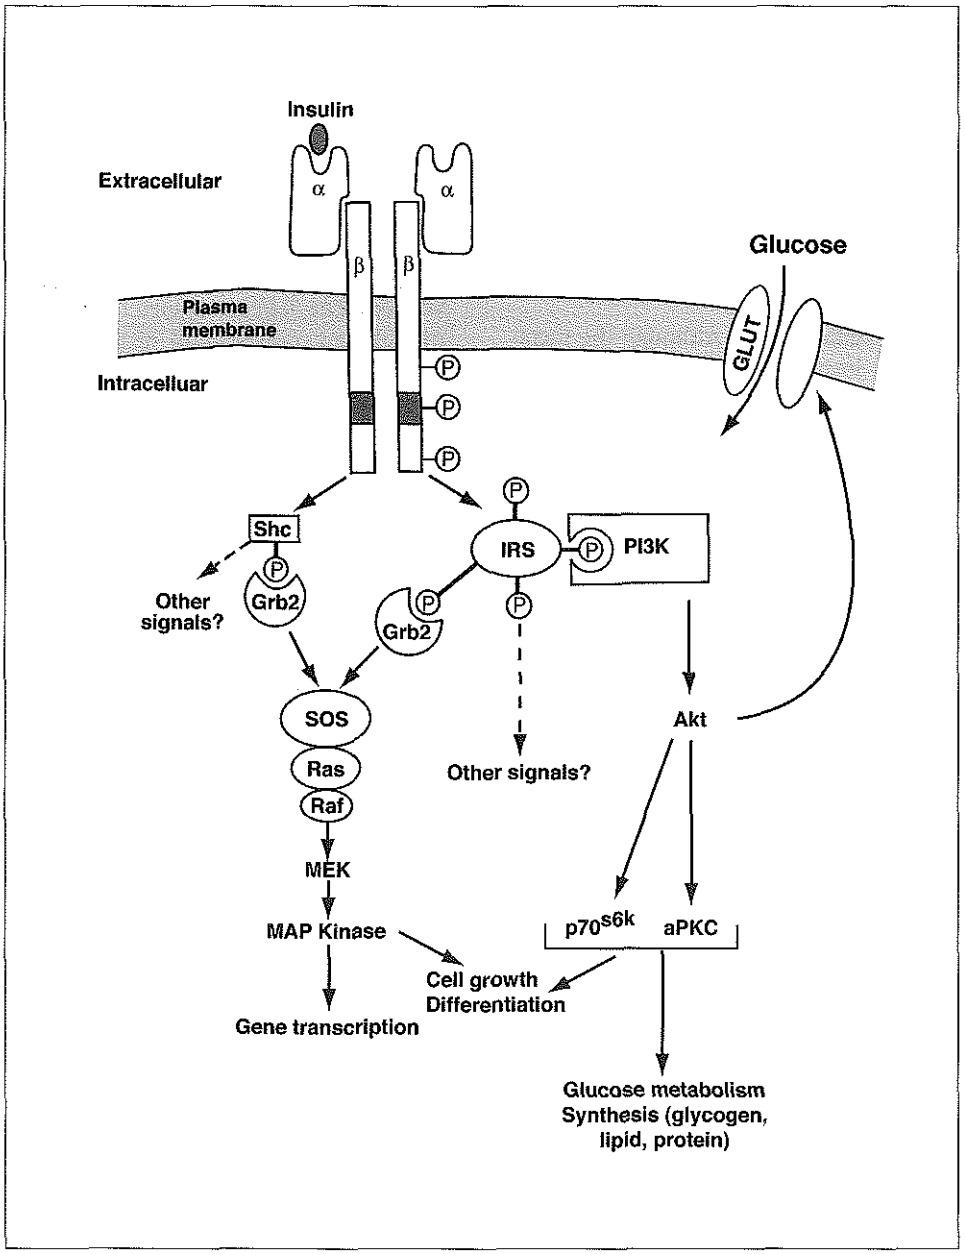

Figure 25-14 Mechanism of insulin action. Binding of insulin to the extracellular α-subunit of the insulin receptor induces autophosphorylation of the β-subunit of the receptor and phosphorylation of selected intracellular proteins, such as Shc and the IRS family. These latter phosphoproteins interact with other targets, thereby activating phosphorylation cascades, which result in glucose uptake (in adipose tissue and skeletal muscle), glucose metabolism, synthesis (of glycogen, lipid, and proteins), enhanced gene expression, cell growth, and differentiation. *p*, protein phosphorylation; *aPKC*, atypical protein kinase C. See text for details.

GLUT1 in the blood-brain barrier and GLUT3 in neuronal cells provide the constant high concentrations of glucose required by the brain. GLUT2 is expressed in hepatocytes, β-cells of the pancreas, and basolateral membranes of intestinal and renal epithelial cells. It is a low-affinity, high-capacity transport system to allow non–rate-limiting movement of glucose into and out of these cells. GLUT4 catalyzes the rate-limiting step for glucose uptake and metabolism in skeletal muscle, the major organ of glucose consumption. When circulating insulin concentrations are low, most of the GLUT4 is localized in intracellular compartments and is inactive. After eating, the pancreas releases insulin, which stimulates the translocation of GLUT4 to the plasma membrane, thereby promoting glucose uptake into skeletal

muscle and fat. Insulin-stimulated glucose transport into skeletal muscle is defective in type 2 diabetes mellitus, but the mechanism has not been established. GLUT6 is a pseudogene that is not expressed at the protein level. GLUT7 allows the diffusion of free glucose out of the endoplasmic reticulum of gluconeogenic tissue.

Insulin-Like Growth Factors

Insulin-like growth factors I and II (IGF I and II) are polypeptides structurally related to insulin.[161] These hormones (previously referred to as *nonsuppressible insulin-like activity* or *somatomedin*) exhibit metabolic and growth-promoting effects similar to those of insulin. IGF I (previously somatomedin C) is one of the major regulators of cell growth and differentiation, but the physiological role of IGF II is not known. Synthesis of IGF I depends on growth hormone and occurs predominantly in the liver. In addition, many other cells produce IGF I that does not enter the circulation but acts locally. Circulating IGF concentrations are approximately 1000-fold higher than insulin concentrations, and the hormone is kept inactive by binding to a family of at least six specific binding proteins.[135] These proteins regulate IGF by protecting the ligands in the circulation and delivering them to their target tissue. In contrast to insulin, which is unbound in the circulation, less than 10% of total serum IGF I is free. The biological actions of IGF are exerted through specific IGF receptors or the insulin receptor. The IGF I receptor is closely related to the insulin receptor in structure and biochemical properties. In contrast, the IGF II receptor is quite different; it lacks tyrosine kinase activity and its physiological relevance is not understood. The IGF I receptor has a high affinity for both IGF I and IGF II, but a low affinity for insulin. The IGF II receptor has high, low, and no affinity for IGF II, IGF I, and insulin, respectively. The insulin receptor binds insulin with high affinity and IGF I and II with low affinity.

The significance of IGFs in normal carbohydrate metabolism is not known. Exogenous administration produces hypoglycemia, whereas a deficiency of IGF I results in dwarfism (pygmies and Laron dwarfs). IGFs, particularly IGF II, may be produced in excess by extrapancreatic neoplasms, and patients may have fasting hypoglycemia.[70] The high concentrations of both IGF II protein in the blood and IGF II messenger RNA (mRNA) in tumor extracts has led to the proposal that IGF II is the humoral mediator of nonislet cell tumor-induced hypoglycemia.[257] Measurement of plasma IGF I concentration may be useful in evaluating growth hormone deficiency and excess and in monitoring responses to nutritional support.

Counterregulatory Hormones

Several hormones have actions opposite to those of insulin. These counterregulatory hormones are catabolic and increase hepatic glucose production initially by enhancing the breakdown of glycogen to glucose (glycogenolysis) and later by stimulating the synthesis of glucose (gluconeogenesis).[99,100] The initial response (within minutes) to low blood glucose is an increase in glucose production, stimulated by glucagon and epinephrine. With time (3 to 4 hours), growth hormone and cortisol increase glucose mobilization and decrease glucose use (see Figure 25-10). Evidence also suggests glucose production by the liver as an inverse function of ambient glucose concentration, independent of hormonal factors *(glucose autoregulation)*. The role of other hormones or neurotransmitters is not clear but appears relatively unimportant. The multiple counterregulatory hormones exhibit both redundancy and hierarchy. Glucagon is the most important, and epinephrine becomes critical when glucagon is deficient. The other factors have lesser roles. These hormones, briefly described here, are discussed further in Chapters 29 and 48.

Glucagon. Glucagon is a 29–amino acid polypeptide secreted by the α-cells of the pancreas. The major target organ for glucagon is the liver, where it binds to specific receptors and increases both intracellular adenosine-5′-monophosphate and calcium. Glucagon stimulates the production of glucose in the liver by glycogenolysis and gluconeogenesis.[168] In addition, glucagon enhances ketogenesis in the liver. A minor target organ for glucagon is adipose tissue, where the hormone increases lipolysis. Glucagon secretion is regulated primarily by plasma glucose concentrations, low and high plasma glucose being stimulatory and inhibitory, respectively. Long-standing diabetes mellitus impairs the glucagon response to hypoglycemia, resulting in an increased incidence of hypoglycemic episodes. Stress, exercise, and amino acids induce glucagon release. Insulin inhibits glucagon release from the pancreas and decreases glucagon gene expression, thereby attenuating its biosynthesis. Increased glucagon concentrations, secondary to insulin deficiency, are believed to contribute to the hyperglycemia and ketosis of diabetes.

Proglucagon is also produced in the distal gut by L-cells, which process it into glucagon, glucagon-like peptide I, and glucagon-like peptide II. Food ingestion stimulates release of glucagon-like peptide I, which acts on the β-cell of the pancreas to stimulate insulin gene transcription and potentiate glucose-induced insulin secretion.

Epinephrine. Epinephrine, a catecholamine secreted by the adrenal medulla, stimulates glucose production (glycogenolysis) and decreases glucose use, thereby increasing blood glucose concentrations. It also stimulates glucagon secretion and inhibits insulin secretion by the pancreas (see Figure 25-10). Epinephrine appears to have *a key role in glucose counterregulation when glucagon secretion is impaired* (e.g., in type 1 diabetes mellitus). Physical or emotional stress increases epinephrine production, releasing glucose for energy. Tumors of the adrenal medulla, known as *pheochromocytomas,* secrete excess epinephrine or norepinephrine and produce moderate hyperglycemia as long as glycogen stores are available in the liver.

Growth Hormone. Growth hormone is a polypeptide secreted by the anterior pituitary gland. It stimulates gluco-

neogenesis, enhances lipolysis, and antagonizes insulin-stimulated glucose uptake.

Cortisol. Cortisol, secreted by the adrenal cortex in response to adrenocorticotropic hormone (ACTH), stimulates gluconeogenesis and increases the breakdown of protein and fat. Patients with Cushing's syndrome have *increased cortisol* owing to a tumor or hyperplasia of the adrenal cortex and may become hyperglycemic. In contrast, people with Addison's disease have *adrenocortical insufficiency* because of destruction or atrophy of the adrenal cortex and may exhibit hypoglycemia.

Other Hormones Influencing Glucose Metabolism

Thyroxine. Thyroxine, secreted by the thyroid gland, is not directly involved in glucose homeostasis but stimulates glycogenolysis and increases the rate of both gastric emptying and intestinal glucose absorption. These factors may produce glucose intolerance in thyrotoxic individuals, but patients usually have a fasting plasma glucose concentration in the reference interval.

Somatostatin. Somatostatin, also called growth hormone–inhibiting hormone, is a 14–amino-acid peptide found in the gastrointestinal tract, the hypothalamus, and the δ-cells of the pancreatic islets. Although somatostatin does not appear to have a direct effect on carbohydrate metabolism, it inhibits the release of growth hormone from the pituitary. In addition, *somatostatin inhibits secretion of glucagon and insulin by the pancreas*, thus modulating the reciprocal relationship between these two hormones.

BOX 25-1 Clinical Utility of Insulin, Proinsulin, C-Peptide, and Glucagon Assays

Insulin
Evaluation of fasting hypoglycemia
Evaluation of the polycystic ovary syndrome
Classification of diabetes mellitus
Predict diabetes mellitus
Assessment of β-cell activity
Select optimal therapy for diabetes
Investigation of insulin resistance
Predict the development of coronary artery disease

Proinsulin
Diagnosis of β-cell tumors
Familial hyperproinsulinemia
Cross-reactivity of insulin assays

C-Peptide
Evaluation of fasting hypoglycemia
  β-cell tumors
  Factitious
Classification of diabetes mellitus
Assessment of β-cell activity
Obtain insurance coverage for insulin pump
Monitoring therapy
  Pancreatectomy
  Transplant (pancreas-islet cell)

Glucagon
Diagnosis of α-cell tumors

Clinical Utility of Measuring Insulin, Proinsulin, C-Peptide, and Glucagon

Box 25-1 lists the clinical conditions in which hormones that regulate glucose, namely insulin, proinsulin, C-peptide, and glucagon, have been measured. Although there is interest in the possible clinical value of measurement of the concentrations of insulin and its precursors, the assays are useful primarily for research purposes. There is no role for routine testing for insulin, proinsulin, or C-peptide in patients with diabetes mellitus.[241] It must be emphasized that the diagnostic criteria for diabetes mellitus do not include measurements of hormones, which remain predominantly research tools.

Insulin

The primary clinical application of insulin measurement is in the evaluation of patients with fasting hypoglycemia (discussed in more detail later in this chapter). Insulin determination has also been proposed to be of value in selecting the optimal initial therapy for patients with type 2 diabetes mellitus. In theory, the lower the pretreatment insulin concentration, the more appropriate might be insulin or an insulin secretagogue as the treatment of choice. Although intellectually appealing, there is no evidence that knowledge of the insulin concentration leads to more efficacious treatment. Evidence indicates that increased concentrations of insulin in nondiabetic individuals predict the development of coronary artery disease.[113] Nevertheless, it is not clear that the increased insulin is responsible for the risk of coronary disease, and the clinical value is questionable.[241] An emerging use for insulin assays is in the evaluation and management of patients with the polycystic ovary syndrome.[241] Women with this condition have insulin resistance and abnormal carbohydrate metabolism that may respond to oral hypoglycemic agents. Although a few investigators have recommended measuring insulin along with glucose during an oral glucose tolerance test as an aid to the early diagnosis of diabetes mellitus, this approach is not recommended.[241]

Proinsulin

High proinsulin concentrations are usually noted in patients with benign or malignant β-cell tumors of the pancreas. Most patients with β-cell tumors have increased insulin, C-peptide, and proinsulin concentrations, but occasionally only proinsulin is increased[98] because the tumors have defective conversion of proinsulin to insulin. Despite its low biological activity, proinsulin production may be adequate to produce hypoglycemia. In addition, a rare form of familial hyperproinsulinemia, produced by impaired conversion to insulin, has been described. Measurement of proinsulin can

be useful to determine the extent of proinsulin-like material that cross-reacts in an insulin assay. Patients with type 2 diabetes have increased proportions of proinsulin and proinsulin conversion intermediates,[167] high concentrations of which are associated with cardiovascular risk factors.[197] Even relatively mild hyperglycemia produces hyperproinsulinemia, with values greater than 40% of insulin concentration in type 2 diabetes.[167] Similarly, women with gestational diabetes mellitus (GDM) have notably higher concentrations of proinsulin and split 32, 33 proinsulin than pregnant normoglycemic control subjects. An increased ratio of proinsulin-like molecules to insulin-like molecules at screening may be a better predictor of GDM than age, obesity, or hyperglycemia.[266] Increased proinsulin concentrations may also be detected in patients with chronic renal failure, cirrhosis, or hyperthyroidism.

Accurate measurement of proinsulin has been difficult for several reasons: the blood concentrations are low; antibody production is difficult; most antisera cross-react with insulin and C-peptide, which are present in much higher concentrations; the assays measure intermediate cleavage forms of proinsulin; and reference preparations of pure proinsulin are not readily available. However, a more sensitive nonequilibrium RIA method for measuring proinsulin was developed by adsorbing the initial antiserum with biosynthetic human C-peptide coupled to agarose to eliminate cross-reactivity with C-peptide.[39,120] An enzyme-linked immunosorbent assay (ELISA) has been described that employs an antibody to C-peptide as the coating antibody and antiinsulin antibody for detection.[101] The detection limit is 0.25 pmol/L.[156]

C-Peptide

Measurement of C-peptide has a number of advantages over insulin measurement. Because hepatic metabolism is negligible, C-peptide concentrations are better indicators of β-cell function than is peripheral insulin concentration.[222] Furthermore, C-peptide assays do not measure exogenous insulin and do not cross-react with insulin antibodies, which interfere with the insulin immunoassay.

Fasting Hypoglycemia. The primary indication for measuring C-peptide is for the evaluation of fasting hypoglycemia. Some patients with insulin-producing β-cell tumors, particularly if hyperinsulinism is intermittent, may exhibit increased C-peptide concentrations with normal insulin concentrations. When hypoglycemia is due to surreptitious insulin injection, *insulin* concentrations will be high but C-peptide values will be low[129]; this occurs because C-peptide is not found in commercial insulin preparations and exogenous insulin suppresses β-cell function.

Insulin Secretion. Basal or stimulated (by glucagon or glucose) C-peptide concentrations can provide an estimate of a patient's insulin secretory capacity and rate. For example, diabetic patients with C-peptide concentrations greater than 1.8 μg/L (1.8 ng/mL) after stimulation with glucagon behave clinically like patients with type 2 diabetes, and those with low peak C-peptide values (less than 0.5 μg/L) behave like patients with type 1 diabetes.[123] In rare cases this strategy may be helpful before discontinuation of insulin treatment (e.g., in an obese adolescent). Urinary and fasting serum C-peptide concentrations also appear to be of some value in differentiating patients with type 1 diabetes from those with type 2 diabetes.[147] In addition, patients who have type 1 diabetes but who have no C-peptide response are usually more labile than those with some residual β-cell function. Despite these observations, C-peptide measurement has a negligible role in the routine management of patients with diabetes. A new indication for C-peptide analysis is the recent requirement that Medicare patients in the United States have low C-peptide concentrations to be eligible for coverage of insulin pumps.[241]

Monitoring Therapy. Measurement of C-peptide can be used to monitor patients' response to pancreatic surgery. C-peptide should be undetectable after a radical pancreatectomy and should increase after a successful pancreas or islet cell transplant.

Measurements of urine C-peptide are useful when a continuous assessment of β-cell function is desired or frequent blood sampling is not practical. The 24-hour urine C-peptide content (in the absence of renal failure, which produces increased levels) correlates well with fasting serum C-peptide concentration or with the sum of C-peptide concentrations in sequential specimens after a glucose load. However, the fraction of secreted C-peptide that is excreted in the urine exhibits high intersubject and intrasubject variability, limiting the value of urine C-peptide as a measure of insulin secretion.[275]

Glucagon

Very high concentrations of glucagon are seen in patients with α-cell tumors of the pancreas called glucagonomas. Patients with this tumor frequently have weight loss, necrolytic migratory erythema, diabetes mellitus, stomatitis, and diarrhea.[289] The skin lesions often occur first and are frequently overlooked. Most tumors have metastasized when finally diagnosed. Low glucagon concentrations are associated with chronic pancreatitis and long-term sulfonylurea therapy.

Methods for the Measurement of Specific Hormones

Details of the following methods for specific hormones are found in the Evolve site that accompanies this book at http://evolve.elsevier.com/Tietz/textbook/.

Insulin

Although insulin has been assayed for more than 40 years, there is no highly accurate, precise, and reliable procedure available to measure the amount of insulin in a patient sample. Many insulin assays are commercially available.[61] The techniques most widely used in the United States are immunochemical.[235] Bioassays, although of greater physiological relevance because they measure biological activity, are labor intensive and not widely used. A stable isotope dilu-

tion mass spectrometry assay, which was described recently, yields lower values than immunoassays.[154]

Patients treated with exogenous insulin may develop circulating antiinsulin antibodies, which compete with antibodies in the RIA. The endogenous antibodies and their bound insulin can be precipitated from serum with polyethylene glycol (PEG), and the free insulin measured by RIA. The total insulin can be determined by eluting antibody-bound insulin with hydrochloric acid (HCl), precipitating the antibody with PEG, and performing RIA. The bound insulin is the difference between total and free insulin. Unless a patient's insulin requirements change dramatically, total insulin concentrations are usually constant in patients with type 1 diabetes, and repeated assays are not necessary.

Principle. In a typical RIA procedure for measuring insulin, ^{125}I-labeled insulin competes with insulin in a patient sample for binding to an insulin-specific antibody immobilized on the walls of a polypropylene tube. The supernatant is decanted, and the bound ^{125}I determined in a gamma counter. The amount of insulin in the sample is established by comparison with a calibration curve obtained by plotting on logit-log graph paper the percent of total radioactivity bound (B/T%) against the concentration of the calibrators. Various commercial kits for insulin measurement are now available.

Comments. General comments on the measurement of insulin include:

1. The term *immunoreactive insulin* is used in reference to assays that may recognize, in addition to insulin, substrates that share antigenic epitopes with insulin. Examples include proinsulin, proinsulin conversion intermediates, and insulin derivatives, produced by glycation or dimerization.
2. Various insulin preparations, including human insulin, are used as insulin calibrators. For ease of comparison of results among laboratories, the insulin calibrator is expressed in terms of international units (IU). One international unit of insulin is equal to approximately 43 μg of the World Health Organization (WHO) first International Reference Preparation (1st IRP) Code 66/304 (National Institute of Biological Standards and Control, South Mimms, Potters Bar, Hertfordshire, United Kingdom), which is 100% human insulin.
3. *Antisera raised against insulin show some cross-reactivity with proinsulin but not with C-peptide.* Specificity is not a problem in healthy individuals because the low proinsulin concentrations do not appreciably affect the absolute values of insulin. In certain situations (e.g., islet cell tumors and diabetic individuals), proinsulin is present at higher concentrations and direct assay of plasma may falsely overestimate the true insulin concentration. Because proinsulin has very low activity, incorrect conclusions regarding the availability of biologically active insulin may be reached in patients with diabetes. The magnitude of the error depends on the concentration of proinsulin and the extent of cross-reactivity of the antiserum with proinsulin. Monoclonal antibody-based assays that are specific for insulin and do not measure proinsulin,[272] although theoretically advantageous, are not superior to nonspecific assays.[235]
4. A stable isotope dilution assay using mass spectrometry to measure insulin, proinsulin, and C-peptide has been developed.[154] The difference in mass among the three analytes allows specific measurement of each protein. Comparison of patient samples revealed that most, but not all, results were higher by immunoassay than mass spectrometry.[154] Thus immunoassays may overestimate insulin, particularly at low concentrations. The high protein concentration in the serum requires extraction of proteins (e.g., by immunoaffinity) and purification by high-performance liquid chromatography (HPLC) before quantification by mass spectrometry. This method is not suitable for routine laboratory analysis.
5. The American Diabetes Association (ADA) appointed a task force to standardize the insulin assay.[235] Evaluation of unknown samples by 17 different laboratories revealed a wide range in insulin values, with interlaboratory variation of up to threefold.[235] Large differences were observed even among laboratories using the same assays. Use of a common calibrator did not improve agreement among laboratories. Assay coefficients of variation (CVs) ranged from less than 2% to greater than 30%, with ELISAs exhibiting the lowest imprecision. Certain characteristics of some assays, including commercial kits, were unacceptable. The task force judged available proficiency and certification programs for insulin to be inadequate, and recommended the establishment of a central laboratory to provide certification for insulin assays. Complete interlaboratory standardization was deemed to be neither practical nor universally acceptable. The ADA recommendations for analysis of insulin[235] are as follows:
   a. Each laboratory should carefully evaluate its insulin assay to ensure acceptable assay performance.
   b. Each laboratory should compare the performance of its assay with others using common calibrators and unknown samples.
   c. Because assay performance may change with time or with new reagents or equipment, performance characteristics must be remeasured periodically.
6. Acceptance criteria for an insulin assay are less than 15% interassay CV. Minimum detectable concentration of insulin, as calculated from the calibration curve, should be 1 μIU/mL with the overnight procedure or 3 μIU/mL with the same-day procedure. In addition, recovery and linearity should be 100 ± 15%, and the in-house insulin calibrator should be within 5% of the gold standard. No gold standard was specified.
7. Patient samples with high values should be diluted with the zero calibrator.
8. The presence of antibodies to insulin results in spuriously increased or decreased (depending on the method used) insulin values.

Reference Intervals. Reference intervals vary among assays and each laboratory should establish its own reference intervals. After an overnight fast, insulin concentrations in healthy, normal, nonobese people range from 2 to 25 μIU/mL (12 to 150 pmol/L).* More specific assays that have minimal cross-reactivity with proinsulin reveal a fasting plasma insulin concentration of less than 9 μIU/mL (60 pmol/L). Concentrations up to 200 μIU/mL can be reached during a glucose tolerance test. Representative values for insulin concentrations after glucose are shown in Figure 25-13. Fasting insulin values are higher in obese, nondiabetic people and lower in trained athletes.

Insulin Antibodies

Assays for insulin antibodies fall into three categories: (1) quantitative radioimmunoelectrophoresis, which measures the binding of IgG antibody to radiolabeled insulin by rocket immunoelectrophoresis into anti–IgG-containing agarose; (2) RIAs with separation of bound and free insulin by precipitation with PEG or a second antibody; and (3) solid phase immobilization of insulin to test tubes or Sepharose. These are discussed in more detail in Reeves.[230]

Proinsulin

Principle. Accurate measurement of proinsulin has been difficult for several reasons: the blood concentrations are low; antibody production is difficult; most antisera cross-react with insulin and C-peptide, which are present in much higher concentrations; the assays measure intermediate cleavage forms of proinsulin; and reference preparations of pure proinsulin were not readily available.[285] Therefore few accurate data are available in the literature on plasma proinsulin. These problems have, to a large extent, been overcome by the availability of biosynthetic proinsulin, which has allowed the production of monoclonal antibodies to proinsulin[79,260] and provided reliable proinsulin calibrators and reference preparations. An International Reference Preparation for human proinsulin (code 84/611) is available from the National Institute of Biological Standards and Controls (Potters Bar, United Kingdom). Earlier assays may have overestimated proinsulin concentrations.[211]

Reference Intervals. Reference intervals for proinsulin are highly dependent on the method of analysis, the degree of cross-reactivity of the antisera, and the purity of proinsulin calibrators. Each laboratory should establish its own reference intervals.

Reference intervals in healthy, fasting individuals reported in the literature range from 1.1 to 6.9 pmol/L to 2.1 to 12.6 pmol/L (see Reference 130 and references therein).

*The conversion factor of 6.0 used to convert μIU/mL (or mIU/L) of insulin to pmol/L is based on a MW of insulin of 5807.58 and a specific activity of 30 IU/mg.

C-Peptide

Principle. C-peptide undergoes minimal liver metabolism and, in contrast to proinsulin assays, assays are not affected by antiinsulin antibodies. However, various methodological problems produce large between-method variation. These difficulties include variable specificity among different antisera, variable cross-reactivity with proinsulin, and the type of C-peptide preparation used as a calibrator. A comparison, in the clinically relevant range, using four commercial kits and four commercial C-peptide antisera yielded values ranging from 0.54 to 1.06 nmol/L on the same sample. Furthermore, a tyrosine residue must be incorporated onto the C-peptide to enable labeling with ^{125}I. Several immunometric methods have been described for the measurement of C-peptide, and a number of kits are commercially available.[61]

Reference Intervals. Each laboratory should establish its own reference interval for C-peptide. Fasting serum concentrations of C-peptide in healthy people range from 0.78 to 1.89 ng/mL (0.25 to 0.6 nmol/L). After stimulation with glucose or glucagon, values range from 2.73 to 5.64 ng/mL (0.9 to 1.87 nmol/L), three to five times the prestimulation value. Urinary C-peptide is usually in the range of 74 ± 26 μg/L (25 ± 8.8 μmol/L). C-peptide is excreted primarily by the kidney and concentrations in the serum are increased in renal disease.

Glucagon

Principle. A competitive RIA is available for measuring glucagon (Diagnostic Products Corp.). ^{125}I-labeled glucagon competes with glucagon in the patient specimen for binding to the polyclonal glucagon antibody. Bound glucagon is separated from free glucagon by use of PEG and a second antibody. Bound radioactivity for the patient specimen is compared with that of glucagon calibrators. The calibrator values are assigned at the manufacturer using the WHO glucagon international standard (69/194).

Reference Intervals. Fasting plasma concentrations of glucagon vary from 70 to 180 ng/L (20 to 52 pmol/L). Values up to 500 times the upper reference limit may be found in patients with autonomously secreting α-cell neoplasms.

DIABETES MELLITUS

Diabetes mellitus is a group of metabolic disorders of carbohydrate metabolism in which glucose is underused, producing hyperglycemia. Some patients may experience acute life-threatening hyperglycemic episodes, such as ketoacidosis or hyperosmolar coma. As the disease progresses, patients are at increased risk for the development of specific complications, including *retinopathy* leading to blindness, *nephropathy* leading to renal failure, *neuropathy* (nerve damage), and *atherosclerosis*.[200,258] The last may result in stroke, gangrene, and coronary artery disease.

The prevalence of diabetes is unknown. The most recent published information in the United States is from the

Centers for Disease Control and Prevention (CDC), which estimated a prevalence in 2001 of 7.9% in adults.[192] This is equivalent to 16.7 million people. Because at least 30% of all prevalent cases are undiagnosed,[117] the total number may have been almost 22 million. Note that in 1987, the prevalence of diagnosed diabetes was 6.8 million.[225] This large increase in diabetes has been observed globally. The prevalence of diabetes in adults worldwide was estimated to be 4.0% in 1995 and anticipated to rise to 5.4% by the year 2025.[153] The prediction is that in 2025 there will be 300 million adults with diabetes, greater than 75% of whom will live in developing countries. These statistics have led to diabetes being described as "one of the main threats to human health in the twenty-first century."[303] The prevalence of diabetes mellitus increases with age, and approximately half of all cases occur in people older than 55 years. In the United States, ~20% of the population older than 65 years have diabetes.[117] There is racial predilection, and by the age of 65, 33%, 25%, and 17% of Hispanics, blacks, and whites, respectively, in the United States have diabetes mellitus. In 2002 diabetes mellitus was estimated to be responsible for $132 billion in healthcare expenditures in the United States.[125] The direct costs were $92 billion, with 50% of that incurred by those older than 65 years. An estimated 186,000 deaths annually are attributable to diabetes.[125] In fact, American women are twice as likely to die from diabetes mellitus as from breast cancer. Approximately one in five American healthcare dollars spent in 2002 was for people with diabetes mellitus.

Classification

Diabetes was initially diagnosed by the oral glucose tolerance test (OGTT). Values greater than two standard deviations above the mean of the value found in a selected population of healthy volunteers without a family history of diabetes mellitus were accepted as diagnostic. This criterion led to the identification of large numbers of asymptomatic people with abnormally high 1- to 2-hour postload glucose values, but normal fasting blood glucose. They were presumed to have early or mild diabetes mellitus. In 1975 it was estimated that more than half the population older than 60 years was abnormal. Follow-up of these people indicated that most of them with lesser degrees of glucose intolerance did not manifest definite evidence of diabetes mellitus in the next 10 years, and a large percentage returned to normal glucose tolerance.

Most populations have plasma glucose values that exhibit a unimodal, log-normal distribution (i.e., a distribution curve that is skewed to the high end but becomes bell shaped on a logarithmic axis). Ethnic groups with a high prevalence of diabetes, such as the Pima Indians and Nauruans, exhibit bimodal blood glucose distributions.[92] Optimal distinction between normal and diabetic individuals in these groups occurs at a fasting glucose around 140 mg/dL and glucose concentrations greater than 200 mg/dL 2 hours after an oral glucose load. Furthermore the specific microvascular complications of diabetes were believed to be rare in patients with fasting or 2-hour postprandial glucose concentrations less than 140 or 200 mg/dL, respectively. These observations were the basis for the criteria proposed in 1979 by a workgroup of the National Diabetes Data Group[203] and later endorsed by the WHO Committee on Diabetes. Lower cutpoints are used currently.

The 1979 classification scheme recognized two major forms of diabetes: type I (insulin-dependent) diabetes mellitus (IDDM) and type II (non–insulin-dependent) diabetes mellitus (NIDDM).[203] The terms juvenile-onset and adult-onset diabetes were abolished. To base the classification on etiology rather than treatment, the ADA established a workgroup in 1995 to reexamine the classification and diagnosis of diabetes mellitus. The revised classification, published in 1997,[7] eliminates the terms insulin-dependent diabetes mellitus and non–insulin-dependent diabetes mellitus, which are now termed type 1 and type 2 diabetes, respectively (Box 25-2). Furthermore the categories of previous abnormality of glucose tolerance and potential abnormality of glucose tolerance have been eliminated.

Type 1 Diabetes Mellitus (Formerly Insulin-Dependent Diabetes Mellitus [IDDM], Type I, or Juvenile-Onset Diabetes)

Approximately 5% to 10% of all cases of diabetes mellitus are in this category. Patients usually have abrupt onset of symptoms (e.g., polyuria, polydipsia, and rapid weight loss). Patients have insulinopenia (a deficiency of insulin) caused by loss of pancreatic islet β-cells and are dependent on insulin to sustain life and prevent ketosis. Most patients have antibodies that identify an autoimmune process (see later discussion); some patients have no evidence of autoimmunity and are classified as type 1 idiopathic. The peak incidence is in childhood and adolescence. Approximately 75% acquire the disease before age 30 years, but the onset in the remainder may occur at any age. Age at presentation is not a criterion for classification.

Type 2 Diabetes Mellitus (Formerly Non-Insulin-Dependent Diabetes Mellitus [NIDDM], Type II, or Adult-Onset Diabetes

This group comprises approximately 90% of all cases of diabetes. Patients have minimal symptoms, are not prone to ketosis, and *are not dependent on insulin* to prevent ketonuria. *Insulin concentrations may be normal, decreased, or increased,* and most people with this form of diabetes have impaired insulin action. *Obesity* is commonly associated and weight loss alone usually improves the hyperglycemia. However, many individuals with type 2 diabetes may require dietary manipulation, an oral hypoglycemic agent, or insulin to control hyperglycemia. Most patients acquire the disease after age 40, but it may occur in younger people. Type 2 diabetes in children and adolescents is an emerging, significant problem.[10,303] Among children in Japan, type 2 diabetes is now more common than type 1.[303]

Other Specific Types of Diabetes Mellitus

This subclass includes uncommon patients in whom hyperglycemia is due to a specific underlying disorder, such as genetic defects of β-cell function; genetic defects in insulin action; disease of the exocrine pancreas; endocrinopathies (e.g., Cushing's disease, acromegaly, and glucagonoma); the administration of hormones or drugs known to induce β-cell dysfunction (e.g., dilantin and pentamidine) or impair insulin action (e.g., glucocorticoids, thiazides, and β-adrenergics); infections; uncommon forms of immune-mediated diabetes; or other genetic conditions (e.g., Down syndrome, Klinefelter syndrome and porphyria; see American Diabetes Association[7] for a detailed list). This was formerly termed *secondary diabetes.*

Impaired Glucose Tolerance (IGT)

Impaired glucose tolerance is diagnosed in people who have *fasting blood glucose concentrations less than those required* for a diagnosis of diabetes mellitus, but have a plasma glucose response during the OGTT between normal and diabetic states. An OGTT is required to assign a patient to this class. Development of overt diabetes occurs at a rate of 1% to 5% per year, but a large proportion spontaneously revert to normal glucose tolerance. Microvascular disease is quite rare in this group and patients usually do not experience the renal or retinal complications of diabetes. Patients have an increased prevalence of atherosclerosis and mortality from cardiovascular disease.[76]

Impaired Fasting Glucose (IFG)

This new category is analogous to IGT, but is diagnosed by a *fasting* glucose value between that of normal and diabetic individuals. It is a metabolic stage between normal glucose homeostasis and diabetes. As with IGT, persons with IFG are at increased risk for the development of diabetes and cardiovascular disease. IFG and IGT are not clinical entities, but rather risk factors for diabetes and cardiovascular disease.

Gestational Diabetes Mellitus

This is carbohydrate intolerance of variable severity *with onset or first recognition during pregnancy*[187] (i.e., diabetic women who become pregnant are not included in this category). Estimates of the frequency of abnormal glucose tolerance during pregnancy range from 1% to 14%, depending on the population studied and the diagnostic tests employed.[153] In the United States, GDM occurs in 6% to 8% of pregnancies. Women with GDM are at increased risk for the subsequent development of diabetes mellitus, which develops in 6% to 62% of these women.[213] The risk is particularly high in women who have marked hyperglycemia during or soon after pregnancy, women who are obese, and women whose GDM was diagnosed before 24 weeks of gestation.[157] At 6 to 12 weeks postpartum, all patients who had GDM should be evaluated for diabetes and, if diabetes is not present, reevaluated for diabetes at least every 3 years.[12]

Pathogenesis of Type 1 Diabetes Mellitus

Type 1 diabetes mellitus results from a cellular-mediated autoimmune destruction of the insulin-secreting cells of pancreatic β-cells.[19,118] In the vast majority of patients, the destruction is mediated by T cells. This is termed type 1A or immune-mediated diabetes (Box 25-2). The α-, δ-, and other islet cells are preserved. The islet cells have a chronic mononuclear cell infiltrate, called *insulitis.* The autoimmune process leading to type 1 diabetes begins months or years before the clinical presentation, and an 80% to 90% reduction in the volume of the β-cells is required to induce symptomatic type 1 diabetes. The rate of islet cell destruction is variable and is usually more rapid in children than in adults.

Antibodies

The most practical markers of β-cell autoimmunity are circulating antibodies, which can be detected in the serum years before the onset of hyperglycemia. The best characterized antibodies are[19,118,241]

1. *Islet cell cytoplasmic antibodies* (ICAs) react with a sialoglycoconjugate antigen present in the cytoplasm of all endocrine cells of the pancreatic islets. These antibodies are detected in the serum of 0.5% of normal subjects and 75% to 85% of patients with newly diagnosed type 1 diabetes. The antibodies are detected by immunofluorescence microscopy on frozen sections of human pancreatic tails. Results are compared with a standard serum of the Immunology of Diabetes Workgroup[190] and are expressed in Juvenile Diabetes Foundation (JDF) units. Although not universal, many laboratories use 10 JDF units on two separate occasions or a single result of greater than or equal to 20 JDF units as significant titers. The ICA assay is labor intensive and difficult to standardize. Few clinical laboratories are likely to implement this assay, which has marked interlaboratory variability in sensitivity and specificity.[241]

2. *Insulin autoantibodies* (IAAs) are present in more than 90% of children who develop type 1 diabetes before age 5, but in fewer than 40% of individuals developing diabetes after age 12. Their frequency in healthy people is similar to that of ICA. A radioisotopic method that calculates the displaceable insulin radioligand binding after the addition of excess nonradiolabeled insulin is recommended for IAA. Results are positive when concentrations exceed the mean +2 (or 3) standard deviations (SD) of healthy controls. An important caveat is that insulin antibodies develop after insulin therapy, even in those persons who use human insulin.
3. *Antibodies to the 65-kD isoform of glutamic acid decarboxylase* (GAD_{65})[21] have been found up to 10 years before the onset of clinical type 1 diabetes and are present in ~60% of patients with newly diagnosed diabetes. GAD_{65} antibodies may be used to identify patients with apparent type 2 diabetes who will subsequently progress to type 1 diabetes. Several different assay formats have been used for the measurement of anti-GAD_{65} antibodies, including enzymatic immunoprecipitation assay, radiobinding assay, ELISA, immunofluorescence, and Western blotting.[252] The considerable variability among laboratories has been significantly reduced by the Second International GADAb Workshop.[252] A monoclonal antibody, MICA 3, was suggested as a reference standard. A dual micromethod and RIA performed with ^{3}H-labeled human recombinant GAD_{65} in a rabbit reticulocyte expression system is used by many laboratories. Methods for measurement of GAD_{65} are now commercially available.
4. *Insulinoma-associated antigens* (IA-2A and IA-2βA), directed against two tyrosine phosphatases, have been detected in more than 50% of newly diagnosed type 1 diabetes patients. A widely used method to measure IA-2A uses ^{35}S-labeled recombinant IA-2 in a dual micromethod and RIA. The concurrent analysis of IA-2 and GAD_{65} in a single assay has been reported.[242]

Although antibodies to bovine serum albumin have been reported in patients with newly diagnosed type 1 diabetes,[146] this model is contentious, and conflicting data exist.[18,20]

The CDC is working with the Immunology of Diabetes Society to develop the Diabetes Autoantibody Standardization Program. Because of the difficulty in obtaining adequate patient samples, it is not yet clear whether this program will become generally available.

Autoantibody markers of immune destruction are present in 85% to 90% of individuals with immune-mediated diabetes when fasting hyperglycemia is initially detected.[7] Approximately 10% to 12% of white adult patients who have the type 2 diabetes phenotype also have islet cell autoantibodies, particularly to GAD_{65}. This condition has been termed latent autoimmune diabetes of adulthood (LADA).[224] Up to 1% to 2% of healthy individuals have a single autoantibody and are at low risk of developing immune-mediated diabetes. Because the prevalence of immune-mediated diabetes is low (~0.3% in the general population), the positive predictive value of a single autoantibody will be low. The presence of multiple islet autoantibodies (IAA, GAD_{65}, and IA-2A and/or IA-2βA) is associated with a greater than 90% risk of immune-mediated diabetes. However, no acceptable therapy has been documented to prevent the clinical onset of diabetes in islet cell autoantibody-positive individuals.[19] New strategies for treatment of type 1 diabetes that are being developed focus on immunosuppressive therapy to attenuate the autoimmune response, replacement of insulin-producing β-cells by transplantation, or restoration of insulin with gene therapy.[102,207] Recently, hyperglycemia in diabetic mice was completely reversed by gene therapy that induced the development of β-cells of the pancreas in the liver.[160] Although type 1 diabetes can be prevented in animal models,[38] the possible role of immune intervention in humans remains unresolved.

Genetics

Susceptibility to type 1 diabetes is inherited,[276] but the mode of inheritance is complex and has not been defined. It is a multigenic trait, and the major locus is the major histocompatibility complex on chromosome 6. At least 11 other loci on 9 chromosomes also contribute, with the regulatory region of the insulin gene on chromosome 11p15 being an important locus. The concordance rate between identical twins is approximately 30%, and approximately 95% of whites with type 1 diabetes express either HLA-DR3 or HLA-DR4 histocompatibility antigens. However, up to 40% of the nondiabetic population also express these alleles. In contrast, the HLA-DQB1*0602 allele significantly decreases the risk of type 1 diabetes. HLA typing can indicate absolute risk of diabetes.[241] The risk of a sibling developing diabetes is 1%, 5%, and 10% to 20% if the number of haplotypes shared is none, one, and two, respectively. However, only 10% of patients with type 1 diabetes have an affected first-degree relative. The multiplicity of independent chromosomal regions associated with a predisposition to type 1 diabetes suggests that other susceptibility genes will be identified. Routine measurement of genetic markers is not of value at this time for the diagnosis or management of patients with type 1 diabetes.[241]

Environment

Reports describe that environmental factors are involved in initiating diabetes. Viruses, such as rubella, mumps, and coxsackievirus B, have been implicated.[136] Other environmental factors that have been suggested include chemicals and cow's milk. It seems likely that autoimmunity to β-cells is initiated by a viral protein (that shares amino acid sequence with a β-cell protein) or some other environmental insult. Genetic susceptibility and other host factors (e.g., HLA type) determine the progression of the β-cell destruction.

Pathogenesis of Type 2 Diabetes Mellitus

There are at least two major identifiable pathological defects in patients with type 2 diabetes.[77,144,243] One is a decreased

ability of insulin to act on the peripheral tissue. This is called *insulin resistance* and is thought by many to be the primary underlying pathological process. The other is *β-cell dysfunction,* which is an inability of the pancreas to produce sufficient insulin to compensate for the insulin resistance. Thus there is a relative deficiency of insulin early in the disease and absolute insulin deficiency late in the disease. The debate over whether type 2 diabetes is primarily due to a defect in β-cell secretion, peripheral resistance to insulin, or both has been raging for decades. However, there are data to support the concept that insulin resistance is the primary defect, preceding the derangement in insulin secretion and clinical diabetes by as much as 20 years.[144,243] Despite the lack of consensus, it is clear that type 2 diabetes mellitus is an extremely heterogeneous disease and no single cause is adequate to explain the progression from normal glucose tolerance to diabetes. The fundamental molecular defects in insulin resistance and insulin secretion result from a combination of environmental and genetic factors.

Loss of β-Cell Function

The increased β-cell demand induced by insulin resistance is ultimately associated with a progressive loss of β-cell function that is necessary for the development of fasting hyperglycemia. The major defect is a *loss of glucose-induced insulin release* (see Figure 25-13), which is termed *selective glucose unresponsiveness.* Hyperglycemia appears to render the β-cells increasingly unresponsive to glucose (called *glucotoxicity*), and the level of dysfunction correlates with both the glucose concentration and duration of hyperglycemia. Restoration of euglycemia rapidly resolves the defect. Increased free fatty acids in serum have also been implicated in β-cell failure.[30] Other insulin secretory abnormalities in type 2 diabetes include disruption of the normal pulsatile release of insulin and an increased ratio of plasma proinsulin to insulin.[167] More recently, evidence obtained from knockout mice reveals that insulin resistance in the β-cells may contribute to alterations in insulin secretion as occur in type 2 diabetes.[162]

Insulin Resistance

Insulin resistance is defined as *a decreased biological response to normal concentrations of circulating insulin*[90] and is found in both obese, nondiabetic individuals and patients with type 2 diabetes. The underlying pathophysiological defects(s) has (have) not been identified, but insulin resistance is usually attributed to a defect in insulin action. Measurement of insulin resistance in a routine clinical setting is difficult and surrogate measures, namely fasting insulin concentration or the euglycemic insulin clamp,[8] are used to provide an indirect assessment of insulin function. There is a broad clinical spectrum of insulin resistance, ranging from euglycemia (with marked increase in endogenous insulin) to hyperglycemia despite large doses of exogenous insulin.

The insulin resistance syndrome (also known as syndrome X or the metabolic syndrome) is a constellation of associated clinical and laboratory findings, consisting of insulin resistance, hyperinsulinemia, obesity, dyslipidemia (high triglyceride and low HDL cholesterol), and hypertension.[228] The metabolic syndrome is diagnosed if an individual has three or more of the following criteria[87]:

- Abdominal obesity: waist circumference greater than 35 inches (women) or 40 inches (men)
- Triglycerides greater than 150 mg/dL
- HDL cholesterol less than 50 mg/dL (women) or less than 40 mg/dL (men)
- Blood pressure greater than or equal to 130/85 mm Hg
- Fasting plasma glucose (FPG) greater than or equal to 110 mg/dL

Individuals with this syndrome are at increased risk for cardiovascular disease. Several rare clinical syndromes are also associated with insulin resistance. The prototype is the type A insulin resistance syndrome, which is characterized by hyperinsulinemia, acanthosis nigricans, and ovarian hyperandrogenism.

Environment

Environmental factors, such as diet and exercise, are important determinants in the pathogenesis of type 2 diabetes. There is convincing evidence linking obesity to the development of type 2 diabetes, but the association is complex. Although 60% to 80% of patients with type 2 diabetes are obese, diabetes develops in fewer than 15% of obese individuals. In contrast, virtually all obese subjects, even those with normal carbohydrate tolerance, have hyperinsulinemia and are insulin resistant. Other factors, such as family history of type 2 diabetes (genetic predisposition), the duration of obesity, and the distribution of fat are important. Nevertheless, the rising prevalence of diabetes is believed to be a consequence of the increase in obesity (defined as a body mass index greater than or equal to 30 kg/m^2), which was reported to be 20.9% in U.S. adults in 2001.[192] Evaluation of 84,941 healthy women after 16 years in the Nurses' Health Study revealed that obesity was the most important predictor of type 2 diabetes.[131] Compared with women with a body mass index of less than 23, the relative risks of developing diabetes were 38.8 and 20.1 with body mass indexes of greater than or equal to 35 and 30 to 34.9, respectively. Importantly, intervention can delay or prevent the onset of type 2 diabetes. Two randomized studies documented that life-style changes (weight reduction and exercise) in individuals with IGT reduced the incidence of type 2 diabetes.[158,279] Although the weight loss was modest (5% to 7%), the rate of progression to type 2 diabetes was reduced by 58% in both studies.

Interestingly, there is an inverse relationship between the degree of physical activity and the prevalence of type 2 diabetes. For every 500-kcal increase in daily energy expenditure, there is a 6% decrease in the age-adjusted risk of type 2 diabetes. This effect is independent of both body weight and a parental history of diabetes. The mechanism of the protective effect of exercise is thought to be an increased sensitivity to insulin in skeletal muscle and adipose tissue.

Diabetogenes

It is widely acknowledged that genetic factors contribute to the development of type 2 diabetes.[144] For example, the concordance rate for type 2 diabetes in identical twins approaches 100%. Type 2 diabetes is 10 times more likely to occur in an obese person with a diabetic parent than an equally obese person without a diabetic family history. However, the mode of inheritance is unknown, and type 2 diabetes has been described as a "geneticist's nightmare."[204] Many less common diseases (e.g., cystic fibrosis or Duchenne muscular dystrophy) are caused by mutations at a single locus. More common diseases, such as diabetes mellitus, schizophrenia, atherosclerosis, hypertension, and osteoporosis, are not inherited according to simple mendelian rules. These conditions are genetically more complex, and multiple genetic factors interact with exogenous influences (such as environmental factors) to produce the phenotype.

Multiple factors complicate the search for diabetogenes in type 2 diabetes.[243] A variety of approaches have produced several genes that are associated with type 2 diabetes. However, despite considerable investigative effort to identify the genetic basis of type 2 diabetes mellitus (more than 60 candidate genes have been examined), *genetic defects identified to date account for fewer than 5% of patients with type 2 diabetes.* Therefore the gene or genes causing the common forms of type 2 diabetes remain unknown. The known genes can be conveniently separated into those involved in insulin secretion, those participating in insulin action, and those regulating body weight.

Candidate Insulin Secretion Genes

These include genes that are expressed in β-cells, such as amylin, glucagon-like peptide-1 receptor, glucokinase regulatory protein, and islet-1 protein. The greatest success in the search for diabetogenes has been in maturity-onset diabetes of the young (MODY), a rare group of disorders characterized by nonketotic diabetes.[30,241] The clinical spectrum of MODY is broad, ranging from asymptomatic hyperglycemia to an acute presentation. There are several different types of MODY, which result from mutations in the genes that encode glucokinase (an enzyme that phosphorylates glucose in the β-cell) or several transcription factors. These can be diagnosed by molecular diagnostic testing. Although MODY is not a form of type 2 diabetes, the interest in the genetics of MODY is in the hope that insight will be obtained into type 2 diabetes.

Candidate Insulin-Resistance Genes

Numerous mutations of the insulin receptor have been identified.[90] Many patients with these defects have extreme insulin resistance, but these mutations are exceptionally rare and are usually found in only one patient or a single family. Mutations of substrates for the insulin receptor that cause diabetes are not known. Few mutations have been described in other potential candidate genes, including those coding for GLUT4 and glycogen synthase. The sequencing of the human genome has enabled whole-genome screens to identify chromosomal regions linked with type 2 diabetes in families.[3] Genetic variation in the gene encoding calpain-10 appears to increase diabetes susceptibility in selected populations.

Candidate Body Weight Gene

A gene that is expressed only in adipose tissue (*ob*) has been cloned and its protein product, leptin, has been proposed to be a vital signaling factor regulating body weight homeostasis and energy balance.[114] Leptin is synthesized in adipose tissue and binds to specific receptors in the hypothalamus, regulating appetite and energy intake.[93,179] Plasma leptin concentrations are increased in diabetic mice, and both food ingestion and insulin administration increase leptin mRNA in fasted rats. This latter finding suggests that insulin may be an important mediator of the effects of food intake on *ob* expression, thus providing a possible genetic link between obesity and type 2 diabetes. The mouse *diabetes (db)* gene and rat *fatty (fa)* gene, both of which have a diabetes phenotype, have been shown to be identical to the *ob* gene.[60] However, caution should be exercised in interpreting these findings, because extrapolation from animal studies to human disease is often not straightforward and obesity, like diabetes mellitus, is unlikely to have a monogenic basis. Although certain strains of genetically obese mice have leptin deficiency and lose weight when leptin is replaced, most obese humans have increased leptin concentrations.[179]

Other Factors

Amylin (also called *islet amyloid polypeptide* [IAPP]) is a 37–amino-acid peptide, which is stored in the β-cells of the pancreas and is co-secreted with insulin in response to food ingestion.[126,239] It is the major component of the amyloid deposits in the pancreatic islets in more than 90% of patients with type 2 diabetes.[66] Whether amylin deposition contributes to the pathogenesis or is a consequence of type 2 diabetes remains contentious. In addition, the biological effects of amylin are not clearly defined and are controversial. Intravenous infusions of amylin are reported to increase blood lactate and glucose concentrations, decrease glucose uptake, and produce insulin resistance.[94] However, other investigators failed to observe an acute effect of amylin on blood glucose concentrations.[42] In most studies, the metabolic sequelae of amylin occur at supraphysiological concentrations, suggesting that the effects are pharmacological.[263] Excess amylin is believed by some to contribute to insulin resistance and glucose intolerance in type 2 diabetes, but these patients exhibit variable plasma amylin concentrations. Amylin appears to help regulate glucose metabolism by delaying gastric emptying and suppressing glucagon production. Amylin deficiency may occur in insulinopenic type 2 patients and patients with type 1 diabetes. Several trials of amylin analogues, such as pramlintide, are being conducted. At the present time, there is no clinical value in measuring amylin.[241]

BOX 25-3 Criteria for the Diagnosis of Diabetes Mellitus

Diabetes Mellitus

Any one of the following is diagnostic:*

1. Classic symptoms of diabetes and casual† plasma glucose concentration ≥200 mg/dL (11.1 mmol/L)
2. Fasting‡ plasma glucose ≥126 mg/dL (7 mmol/L)
3. 2-hour postload plasma glucose concentration ≥200 mg/dL during the OGTT (11.1 mmol/L)

Impaired Fasting Glucose

Fasting plasma glucose between 110 and 125 mg/dL (6.1 and 7.0 mmol/L)§

Impaired Glucose Tolerance

Two criteria must be met:

1. Fasting plasma glucose <126 mg/dL (7 mmol/L)
2. 2-hour OGTT plasma glucose concentration is between 140 and 199 mg/dL (7.8 and 11.1 mmol/L)

From the American Diabetes Association. Report of the expert committee on the diagnosis and classification of diabetes mellitus. Diabetes Care 1997; 20:1183-1201.

OGTT, Oral glucose tolerance test.

*If positive, confirm by repeat testing on a subsequent day.

†Regardless of the time of the preceding meal.

‡No caloric intake for at least 8 hr.

§In 2003, the ADA recommended a lower limit for the IFG interval of 100 mg/dL (5.6 mmol/L).

Note: Whole-blood glucose concentrations are approximately 10% to 12% lower than plasma concentrations.

New strategies to elucidate the pathogenesis of diabetes have been adopted recently. The expression of integral components of insulin signaling or secretion has been manipulated in transgenic or knockout mice. These approaches have begun to yield some insight.[28] In addition, DNA microarray technology has been applied to identify differences in gene expression patterns in selected tissues between normal, obese, and diabetic mice.[196,301] Similar endeavors are being adopted to discover new proteins as substrates with therapeutic potential. These techniques may identify novel analytes for diagnosis and targets for the development of new therapeutic agents.

DIAGNOSIS

The diagnosis of diabetes mellitus depends solely on the *demonstration of hyperglycemia* (Box 25-3). For type 1 diabetes, the diagnosis is usually easy because hyperglycemia appears abruptly, is severe, and is accompanied by serious metabolic derangements. Diagnosis of type 2 diabetes may be difficult because the hyperglycemia is often not severe enough for the patient to notice symptoms of diabetes. Nevertheless, the risk of complications makes it important to identify people with the disease.

The diagnostic criteria previously recommended were (1) classic symptoms of diabetes with unequivocal increase of plasma glucose, (2) FPG greater than or equal to 140 mg/dL on more than one occasion, or (3) a 2-hour and one other postload glucose concentration greater than or equal to 200 mg/dL during an OGTT.[203] These criteria were widely adopted but are imperfect. The OGTT is more sensitive than fasting glucose early in the course of type 2 diabetes, resulting in a lack of equivalence between the fasting and 2-hour glucose values. Virtually all persons with an FPG concentration greater than or equal to 140 mg/dL have a 2-hour glucose greater than or equal to 200 mg/dL in an OGTT. In contrast, in persons without previously identified diabetes, a fasting glucose greater than or equal to 140 mg/dL is present in only 25% of those who have a 2-hour glucose greater than or equal to 200 mg/dL. To address these and other discrepancies, the diagnostic criteria were revised in 1997 (see Box 25-3).[7,240] The major modification is that the diagnostic threshold for fasting glucose has been lowered from 140 to 126 mg/dL (7 mmol/L) to better identify individuals at risk of retinopathy and nephropathy. The lower cutoff should result in earlier diagnosis of diabetes, with consequent earlier therapeutic intervention.[240]

Fasting Plasma Glucose Concentrations

FPG concentrations exceeding 126 mg/dL (7 mmol/L) on more than one occasion are diagnostic of diabetes mellitus (see Box 25-3). The diagnosis of most cases of diabetes mellitus can be established with this criterion. However, some investigators believe that hyperglycemia may be a relatively late development in the course of type 2 diabetes, delaying the diagnosis and underestimating the prevalence of diabetes mellitus in the population.[271] Complications of diabetes, such as retinopathy, proteinuria, and neuromuscular disease, are present in approximately 30% of patients at clinical diagnosis of type 2 diabetes, and the onset of type 2 diabetes probably occurs at least 4 to 7 years before clinical diagnosis. Screening of high-risk individuals for diabetes is now recommended.[7,112] Fasting glucose should be measured in all asymptomatic people at age 45 (or younger in subjects at increased risk), with follow-up testing every 3 years (see discussion later in this chapter). However, there is no published evidence that treatment based on screening is efficacious.

Oral Glucose Tolerance Test

Serial measurement of plasma glucose before and after a specific amount of glucose given orally should provide a standard method to evaluate individuals and establish values for healthy and diseased subjects. Although more sensitive than FPG determinations, glucose tolerance testing is affected by a large number of factors that result in *poor reproducibility* (Box 25-4).[4] Moreover, approximately 20% of OGTTs fall into the nondiagnostic category (e.g., only one blood sample exhibits increased glucose concentration). Unless results are grossly abnormal initially, *the OGTT should be performed on two separate occasions* before the results are considered abnormal.

BOX 25-4 Factors Other Than Diabetes That May Influence the Oral Glucose Tolerance Test

Patient Preparation
Duration of fast
Prior carbohydrate intake
Medications (e.g., thiazides, oral contraceptives, and corticosteroids)
Trauma
Intercurrent illness
Age
Activity
Weight

Administration of Glucose
Form of glucose (anhydrous or monohydrate)
Quantity of glucose ingested
Volume in which administered
Rate of ingestion

During the Test
Posture
Anxiety
Caffeine
Smoking
Activity
Time of day

The following conditions should be met for performing an OGTT: discontinue, when possible, medications known to affect glucose tolerance; perform in the morning after 3 days of unrestricted diet (containing at least 150 g of carbohydrate per day) and activity; and perform the test after a 10- to 16-hour fast only in ambulatory subjects (bed rest impairs glucose tolerance), who should remain seated during the test without smoking cigarettes. Glucose tolerance testing should not be performed on hospital, acutely ill, or inactive patients. The test should begin between 7 AM and 9 AM. Plasma glucose should be measured fasting, then every 30 minutes for 2 hours after an oral glucose load. For nonpregnant adults, the recommended load is 75 g, which may not be a maximum stimulus[203]; for children, 1.75 g/kg, up to a 75-g maximum is given. The glucose should be dissolved in 300 mL of water, and ingested over 5 minutes. A commercial, more palatable form of glucose may be ingested, but whether the anhydrous or monohydrate form of glucose should be used is still in question.[291]

An OGTT is rarely necessary for the diagnosis of diabetes mellitus and is not recommended by the ADA for routine clinical use. It continues to be recommended in a limited fashion by the WHO[1,241] and its use remains contentious. The sensitivity of FPG concentrations is lower than the OGTT for diagnosing diabetes, and some authors claim that the OGTT better identifies patients at risk for developing complications of diabetes. An FPG value less than 100 mg/dL or a random glucose concentration less than 140 mg/dL is sufficient to rule out the diagnosis of diabetes mellitus. An OGTT is indicated in the following situations:

1. Diagnosis of GDM (discussed later).
2. Diagnosis of IGT. This remains controversial. Individuals with IGT have increased risk of cardiovascular disease, but many of them do not have IFG by ADA criteria.[241]
3. Evaluation of a patient with unexplained nephropathy, neuropathy, or retinopathy, with random glucose concentration less than 140 mg/dL. Abnormal results in this setting do not necessarily denote a cause-and-effect relationship, and other diseases must be ruled out.
4. Population studies for epidemiological data.

Intravenous Glucose Tolerance Test

Poor absorption of orally administered glucose may result in a "flat" tolerance curve. Some patients are unable to tolerate a large oral carbohydrate load or may have altered gastric physiology (e.g., after gastric resection). In these patients, an intravenous glucose tolerance test may be performed to eliminate factors related to the rate of glucose absorption. In addition, measurement of the first-phase insulin response can identify the subgroup of individuals with increased concentrations of multiple autoantibodies who are at greatest risk of progression to type 1 diabetes.[34]

Preparation of patients is the same as for the OGTT. The dose of glucose is 0.5 g/kg of body weight (maximum 35 g), given as a 25-g/dL solution. The dose is administered intravenously over 3 minutes ± 15 seconds, and blood is collected every 10 minutes after the midinjection time for 1 hour. A single forearm vein cannula may be used for infusion and sampling, but it should be flushed with saline after the glucose is infused and dead space should be cleared with several volumes of blood before each sample is drawn. If insulin assays are performed, a specimen is also obtained 5 minutes after the start of the injection. Blood glucose concentrations decrease in an exponential manner, and the rate of glucose disappearance can be calculated from the formula $K = 70/t_{1/2}$, where $t_{1/2}$ is the number of minutes required for the blood glucose value to decrease to one half of the 10-minute value, and K is the rate of disappearance of blood glucose, expressed as percent per minute. The glucose values are plotted on the log scale of semilog paper versus time on the abscissa. The best-fitting straight line is drawn through the points, and the time (in minutes) for the glucose concentration to decrease 50% ($t_{1/2}$) is read. In healthy individuals, K usually exceeds 1.5%; values less than 1.0% are considered diagnostic of diabetes. A poor correlation is found between the results of intravenous and oral glucose tolerance tests.[96] Like oral glucose tolerance, intravenous glucose tolerance deteriorates with age.

In the formula $K = 70/t_{1/2}$, the value of 70 is derived from the logarithmic nature of the decrease in glucose concentration with time. The concentration of glucose at 10 minutes

will be twice that of the value obtained from the plot $t_{1/2}$. Using natural logarithms, the rate of decrease in glucose concentration, expressed as percent per minute (K), is given by

$$K = 100(\ln 2 - \ln 1)/t_{1/2} = 69.3/t_{1/2} \cong 70/t_{1/2}$$

The main indication for the intravenous glucose tolerance test is in clinical research to evaluate the first-phase insulin response to glucose (see Figure 25-13).[35] The test is performed as described earlier, but samples are drawn as follows:

Two baseline samples 5 minutes apart (the latter immediately before infusion) and samples 1, 3, 5, and 10 minutes after the end of the glucose infusion. The first-phase insulin release is usually measured by the sum of the insulin concentrations 1 and 3 minutes after the glucose bolus. Alternatively, the 0- to 10-minute incremental insulin area may be used. Like the OGTT, the intravenous glucose tolerance test has poor reproducibility.

Gestational Diabetes Mellitus

Normal pregnancy is associated with increased insulin resistance, especially in the late second and third trimesters. Euglycemia is maintained by increased insulin secretion, with GDM developing in those women who fail to augment insulin sufficiently. Risk factors for GDM include a family history of diabetes in a first-degree relative, obesity, advanced maternal age, glycosuria, and selected adverse outcomes in a previous pregnancy (e.g., stillbirth or macrosomia). The recommendations for screening and diagnosis were formulated in 1984 at the Second International Workshop-Conference on Gestational Diabetes Mellitus[264] and refined at the Third and Fourth International Workshop-Conferences in 1990 and 1998,[187] respectively. Based on the last workshop-conference, the ADA modified their recommendations for laboratory diagnosis of GDM by adopting 5% to 10% lower glucose values.[9] Their guidelines are as follows:

1. Low-risk patients require no testing. Low-risk status is limited to women meeting all of the following:
   - Age less than 25 years
   - Weight normal before pregnancy
   - Member of an ethnic group with a low prevalence of GDM
   - No known diabetes in first-degree relatives
   - No history of abnormal glucose tolerance
   - No history of poor obstetric outcome
2. Average-risk patients (all patients who fall between low and high risk) should be tested at 24 to 28 weeks of gestation (see below for testing strategy).
3. High-risk patients should undergo immediate testing. They are defined as having any of the following:
   - Marked obesity
   - Personal history of GDM
   - Glycosuria
   - Strong family history of diabetes

The first step in laboratory testing is identical to that for diagnosing diabetes in a nonpregnant individual (i.e., an FPG greater than or equal to 126 mg/dL (7 mmol/L) or casual plasma glucose greater than or equal to 200 mg/dL (11.1 mmol/L) (see Box 25-3). However, in the absence of that degree of hyperglycemia, average- and high-risk patients receive a glucose challenge test following one of two methods (Table 25-3):

1. One step: Perform either a 100-g or 75-g OGTT. This one-step approach may be cost-effective in high-risk patients or populations (e.g., some Native-American groups).
   - The 100-g OGTT is the most commonly used standard test supported by outcome data.
   - Alternatively, a 75-g OGTT can be performed, but it is not as well validated as the 100-g test, and cutoffs are arbitrary. In the 75-g test, diagnostic criteria for plasma glucose concentrations are the same as for the 100-g test, except that there is no 3-hour measurement (Table 25-3).
2. Two step (Table 25-3): The first step is a 50-g oral glucose load (the patient does not need to be fasting), followed by a plasma glucose determination at 1 hour. A plasma glucose value greater than or equal to 140 mg/dL (7.7 mmol/L) indicates the necessity for definitive testing. Approximately 15% of patients have a 1-hour venous plasma glucose concentration of 140 mg/dL (7.7 mmol/L)

TABLE 25-3 Screening and Diagnosis of Gestational Diabetes Mellitus

Screening

1. Perform between 24 and 28 wk of gestation on all average- and high-risk pregnant women not identified as having glucose intolerance.
2. Give 50 g oral glucose load without regard to time of day or time of last meal.
3. Measure venous plasma glucose at 1 hr.
4. If glucose is ≥140 mg/dL,* perform glucose tolerance test.

Diagnosis

1. Perform in the morning after a 8–14-hr fast.
2. Measure fasting venous plasma glucose.
3. Give 75 or 100 g of glucose orally.
4. Measure plasma glucose hourly for 3 hr (or 2 hr if 75 g of glucose given)
5. At least two values must meet or exceed the following:

	100-g load	75-g load
Fasting	95 mg/dL	95 mg/dL
1 hr	180 mg/dL	180 mg/dL
2 hr	155 mg/dL	155 mg/dL
3 hr	140 mg/dL	—

6. If results are normal in a clinically suspect situation, repeat during the third trimester.

*Some experts recommend a cutoff of 130 mg/dL.

or greater and require a full diagnostic glucose tolerance test. That subgroup includes ~80% of all women with GDM. Some experts have recommended a value of greater than or equal to 130 mg/dL. This cutoff will increase the sensitivity for GDM to greater than 90%, but will include ~25% of all pregnant women. The second and definitive test is one of the two OGTTs described above.

The criteria for diagnosis are different from those for nonpregnant patients (see Table 25-3).[214] There remains a lack of consensus regarding the use of the 100-g versus 75-g OGTT for the definitive diagnosis of GDM. Although the 75-g OGTT appears practical and acceptable, there are more data with the 100-g OGTT. Moreover, appropriate diagnostic thresholds remain in dispute.[187]

Although usually asymptomatic and not life threatening to the mother, GDM is associated with an increased incidence of neonatal mortality and morbidity, including hypocalcemia, hypoglycemia, and macrosomia.[157,187] The maternal hyperglycemia causes the fetus to secrete more insulin, resulting in stimulation of fetal growth and macrosomia. Recognition is important because therapy can reduce the perinatal morbidity and mortality.[201] Maternal complications include a high rate of cesarean delivery and hypertension. In addition, mothers with GDM are at a significantly increased risk of subsequent diabetes, predominantly type 2. The cumulative incidence of type 2 diabetes varies among populations, ranging from ~40% to 70%.[152] It rises markedly in the first 5 years and reaches a plateau after 10 years.

Distinct from GDM is pregnancy in a patient with preexisting diabetes (~19,000 per annum in the United States). This is associated with an increased incidence of congenital malformations, but meticulous glycemic control during the first 8 weeks of pregnancy can significantly decrease the risk of congenital malformations.[155] Tight control results in an increased incidence of maternal hypoglycemia, which is teratogenic in animals but does not cause malformations in humans.[189]

Women with GDM should be evaluated at the first postpartum visit (at least 6 weeks after delivery) for diabetes by standard criteria (see Box 25-3). If glucose values are normal, glycemia should be reassessed at least every 3 years.

Chronic Complications of Diabetes Mellitus

Pathogenesis

Patients with both type 1 and type 2 diabetes are at high risk for the development of chronic complications.[43,200] Diabetes-specific microvascular pathology in the retina, renal glomerulus, and peripheral nerve produces retinopathy, nephropathy, and neuropathy. As a result of these microvascular complications, diabetes is the most frequent cause of new cases of blindness in the industrialized world in persons between 25 and 74 years and the leading cause of end-stage renal disease.[15] Diabetes is also associated with a marked increase in atherosclerotic macrovascular disease involving cardiac, cerebral, and peripheral large vessels. The consequence is that patients with diabetes have a high rate of myocardial infarction (the major cause of mortality in diabetes), stroke, and limb amputation. Prospective clinical studies document a strong relationship between hyperglycemia and the development of microvascular complications.[72,280] Both hyperglycemia and insulin resistance appear to be important in the pathogenesis of macrovascular complications.[43,105,280]

Progress has been made in our understanding of the molecular mechanisms underlying the derangements produced by hyperglycemia.[43,258] Four main hypotheses have been proposed to explain how hyperglycemia causes the neural and vascular pathology. These are: increased aldose reductase (or polyol pathway) flux; enhanced formation of advanced glycation end products (AGE); activation of protein kinase C; and increased hexosamine pathway flux. Inhibitors of each of these have been shown to ameliorate diabetes-induced abnormalities in cell culture and animal models.[43] The overproduction of superoxide by the mitochondrial electron transport chain integrates these four apparently disparate mechanisms. Clinical trials are underway using novel therapies specifically directed at the signaling molecules (such as protein kinase C) or employing antioxidants to neutralize the effects of the oxidants.

Effect of Intensive Therapy

Type 1 Diabetes

Although it had been theorized for many years that better glycemic control would decrease rates of long-term complications of diabetes mellitus, it was not until the publication of the Diabetes Control and Complications Trial (DCCT) in 1993[72] that this hypothesis was verified. The DCCT was a multicenter, randomized trial that compared the effects of intensive and conventional insulin therapy on the development and progression of complications in 1441 patients with type 1 diabetes. During the study period, which averaged 6.5 years, intensively managed patients maintained significantly lower mean blood glucose concentrations. Compared with conventional therapy, intensive therapy reduced the risk of retinopathy, nephropathy, and neuropathy by 40% to 75%.[72] Intensive therapy delayed the onset and slowed the progression of these three complications, regardless of age, gender, or duration of diabetes. The absolute risks of retinopathy and nephropathy were proportional to the mean glycated hemoglobin (GHb) (discussed later in the chapter). Although intensive therapy also reduced the development of hypercholesterolemia, major cardiovascular and peripheral vascular disease were not significantly decreased. This landmark study has had a significant impact on therapeutic goals and comprehension of the pathogenesis of complications of diabetes.

At the conclusion of the DCCT, 95% of the participants enrolled in the long-term follow-up study, termed the Epidemiology of Diabetes Interventions and Complications (EDIC). Five years after the end of the DCCT, there was no difference in metabolic control (assessed by GHb measure-

ments) between the former conventional and intensively treated groups. Nevertheless, the further progression of retinopathy was ~70% lower in the former intensive group, demonstrating that the beneficial effects of intensive treatment persisted for at least several years beyond the period of strictest intervention.[74]

Type 2 Diabetes

The role of hyperglycemia in the development of complications in individuals with type 2 diabetes was established in the United Kingdom Prospective Diabetes Study (UKPDS).[280] The UKPDS was a major randomized, multicenter clinical study that included 5102 patients with newly diagnosed type 2 diabetes who were followed for an average of 10 years. Analogous to the findings of the DCCT, the UKPDS demonstrated in patients with type 2 diabetes that intensive treatment diminishes by ~10% to 40% the development of microvascular complications.[280] Although intensive treatment decreased the rate of occurrence of macrovascular complications, the reduction was not statistically significant. An important caveat of both the DCCT and UKPDS was that intensive therapy produced a threefold increase in the incidence of severe hypoglycemia.[72,280]

Role of the Clinical Laboratory in Diabetes Mellitus

The clinical laboratory has a vital role in both the diagnosis and management of diabetes mellitus. Some of the important parameters assayed are outlined in Table 25-4. In 2002 the National Academy of Clinical Biochemistry (referred to as the NACB) published evidence-based guidelines for laboratory analysis in diabetes mellitus.[241] The guidelines were reviewed by the Professional Practice Committee of the ADA and were consistent in those areas where the ADA also published recommendations. Specific recommendations for laboratory testing based on published data or derived from expert consensus are presented.[241] A brief overview is presented here.

Diagnosis

Preclinical (Screening)

Type 1 Diabetes. Evidence from animal studies suggests that immune intervention therapy before the appearance of clinical symptoms can delay or prevent type 1 diabetes. Several large clinical trials are underway to assess a variety of therapeutic strategies designed to delay or prevent the

TABLE 25-4 Role of the Laboratory in Diabetes Mellitus

Diagnosis	
Preclinical (Screening)	**Clinical**
Immunological markers	Blood glucose
ICA	OGTT
IAA	Ketones (urine and blood)
GAD antibodies	Other (e.g., insulin, C-peptide, and stimulation tests)
Protein tyrosine phosphatase antibodies (IA-2)	
Genetic markers (e.g., HLA)	
Insulin secretion	
Fasting	
Pulses	
In response to a glucose challenge	
Blood glucose	

Management	
Acute	**Chronic**
Glucose	Glucose
Blood	Blood (fasting-random)
Urine	Urine
Ketones	Glycated proteins
Blood	GHb
Urine	Fructosamine
Acid-base status (pH, bicarbonate)	Urinary protein
Lactate	UAE ("microalbuminuria")
Other abnormalities related to cellular dehydration or therapy (e.g., potassium, sodium, phosphate, and osmolality)	Proteinuria
	Evaluation of complications (e.g., creatinine, cholesterol, and triglycerides)
	Evaluation of pancreas transplant (C-peptide, insulin)

onset of type 1 diabetes.[118] The Diabetes Prevention Trial-Type 1 (DPT-1) screened 84,228 relatives of patients with diabetes for islet cell antibodies.[80] Half of the 339 individuals deemed to be at high (greater than 50%) risk for disease were randomly assigned to low-dose insulin therapy. Unfortunately, insulin injections failed to delay the development of type 1 diabetes.[80] Results of the oral arm of the trial have not been reported yet. Despite the negative results, the ADA encourages screening of first-degree relatives of patients with type 1 diabetes by measuring immune-related markers (autoantibodies), provided that individuals who have positive screening results are referred to defined research studies,[13] several of which are underway.[241] Until effective intervention therapy becomes available and cost-effective screening strategies are developed for young children, screening for antibodies is not recommended.[241] Some experts have proposed that testing for islet cell autoantibodies may be useful in the following situations: (1) to identify a subset of adults initially thought to have type 2 diabetes but who have islet cell autoantibody markers of type 1 diabetes and progress to insulin dependency; (2) to screen nondiabetic family members who wish to donate a kidney or part of their pancreas for transplantation; (3) to screen women with GDM to identify those at high risk of progression to type 1 diabetes; and (4) to distinguish type 1 from type 2 diabetes in children to institute insulin therapy at the time of diagnosis.[241] There is wide variability in clinical practice regarding the use of islet-cell autoantibodies. Proponents argue that the results of autoantibody assays are clinically useful, whereas others point to a lack of evidence. Although some clinicians, particularly those who treat pediatric patients, use autoantibody assays, clinical studies are necessary to provide outcome data to validate the clinical use of autoantibody assays.

Screening by determining HLA type is not currently warranted, except in research studies.[241] A decrease in glucose-stimulated insulin secretion is the first functional abnormality in both type 1 and type 2 diabetes. Nevertheless, tests of insulin secretion are not currently recommended for routine clinical use.

Type 2 Diabetes. Screening of asymptomatic individuals for type 2 diabetes has been the subject of much controversy.[112] The ADA, which previously did not support screening, now advocates screening in all asymptomatic individuals over the age of 45 years.[14,86] Screening should be performed, particularly in overweight individuals, by FPG in a healthcare setting. If results are less than 110 mg/dL (6.1 mmol/L), testing should be repeated at 3-year intervals.[241] Testing may be considered at a younger age or be carried out more frequently in individuals at increased risk of diabetes (e.g., family history or a member of certain ethnic groups).[14] The rising incidence of type 2 diabetes in adolescents has led to the recommendation for screening overweight youths with any two of the following risk factors: (1) they have a family history of type 2 diabetes in first- and second-degree relatives; (2) they belong to a certain race and/or ethnic group; or (3) they have signs of insulin resistance.[14,241] Testing should be done every 2 years starting at 10 years of age. Rationales for screening are that at least 33% of individuals with type 2 diabetes are undiagnosed, complications are often present by the time of diagnosis, and treatment delays the onset of complications.[112] Notwithstanding these recommendations, there is no evidence that treatment based on screening has value.

Clinical

The laboratory diagnosis of diabetes is made exclusively by the demonstration of hyperglycemia. Other assays, such as the OGTT, contribute to the classification and characterization. Although other tests (e.g., C-peptide and insulin analysis) have been proposed to assist in the diagnosis and classification of the disease, these do not at present have a role outside of research studies.[241]

Management

Acute

In diabetic ketoacidosis, hyperosmolar nonketotic coma, and hypoglycemia, the clinical laboratory has an essential role in both diagnosis and monitoring of therapy. Several analytes are frequently measured to guide clinicians in treatment regimens to restore euglycemia and correct other metabolic disturbances. The metabolic abnormalities of these conditions are beyond the scope of this book, and interested readers are referred to a standard textbook of medicine. The NACB guidelines also provide information on the tests that are used.

Chronic

The DCCT[72] and UKPDS[280] studies documented a correlation between blood glucose concentrations and the development of long-term complications of diabetes. Measurement of glucose and glycated proteins provides an index of short- and long-term glycemic control, respectively (see section on glycated proteins later in the chapter). The detection and monitoring of complications are achieved by assaying urea, creatinine, urinary albumin excretion, and serum lipids. The success of newer therapies, such as islet cell or pancreas transplantation, can be monitored by measuring serum C-peptide or insulin concentrations.

HYPOGLYCEMIA

Hypoglycemia is a blood glucose concentration below the fasting value, but it is difficult to define a specific limit.[255] The most widely suggested cutoff is 50 mg/dL, but some authors suggest 60 mg/dL.[45] A transient decline may occur 1.5 to 2 hours after a meal, and it is not uncommon for a plasma glucose concentration as low as 40 mg/dL to be observed 2 hours after ingestion of an oral glucose load. Similarly, extremely low fasting blood glucose values may occasionally be noted without symptoms or evidence of underlying disease.

Symptoms of hypoglycemia vary among individuals and none is specific. Epinephrine produces the classic signs and symptoms of hypoglycemia, namely trembling, sweating, nausea, rapid pulse, lightheadedness, hunger, and epigastric discomfort. These autonomic (neurogenic) symptoms are nonspecific and may also be noted in other conditions, such as hyperthyroidism, pheochromocytoma, or even anxiety. Although controversial, it has been proposed that a rapid decrease in blood glucose may trigger the symptoms even though the blood glucose itself may not reach hypoglycemic values, whereas gradual onset of hypoglycemia may not produce symptoms.[78]

The brain cannot store or produce glucose and in resting adults the central nervous system (CNS) consumes approximately 50% of the glucose used by the body.[100] Very low concentrations of plasma glucose (less than 20 or 30 mg/dL) cause severe CNS dysfunction. During prolonged fasting or hypoglycemia, ketones may be used as an energy source. The broad spectrum of symptoms and signs of CNS dysfunction ranges from headache, confusion, blurred vision, and dizziness to seizures, loss of consciousness, and even death; these symptoms are known as *neuroglycopenia.* Restoration of plasma glucose usually produces a prompt recovery, but *irreversible damage may occur.*

The age of onset of hypoglycemia is a convenient way to classify the disorder (Box 25-5), but it should be borne in mind that some overlap occurs among the various groups. For example, some glycogen storage disorders may present in the third decade of life, and hormone deficiencies occur in childhood.

BOX 25-5 Causes of Hypoglycemia

Neonates
Small for gestational age-prematurity
Respiratory distress syndrome
Maternal diabetes mellitus
Toxemia of pregnancy
Other (e.g., cold stress, polycythemia)

Infants
Ketotic hypoglycemia
Congenital enzyme defects
Glycogen storage disease
Deficiency of gluconeogenic enzymes
Galactosemia
Hereditary fructose intolerance
Leucine hypersensitivity
Endogenous hyperinsulinism
Reye's syndrome
Idiopathic

Adults
Medications (insulin, oral hypoglycemic agents)
Toxins (alcohol, hypoglycins)
Severe hepatic dysfunction
Deficiency of hormones (e.g., glucocorticoids, growth hormone)
Insulin-producing pancreatic tumors (insulinoma)
Insulin antibodies
Nonpancreatic neoplasms
Septicemia
Chronic renal failure
Reactive

Hypoglycemia in Neonates and Infants

Neonatal blood glucose concentrations are much lower than adult (mean ≈35 mg/dL) and decline shortly after birth when liver glycogen stores are depleted. Glucose concentrations as low as 30 mg/dL in a term infant and 20 mg/dL in a premature infant may occur without clinical evidence of hypoglycemia. The more common causes of hypoglycemia in the neonatal period include prematurity, maternal diabetes, GDM, and maternal eclampsia (see Box 25-5; for review, see Haymond).[119] These are usually transient. Hypoglycemia with onset in early infancy is usually less transitory and may be due to inborn errors of metabolism or ketotic hypoglycemia, and usually develops after fasting or a febrile illness.

Fasting Hypoglycemia in Adults

Hypoglycemia may result from a *decreased* rate of hepatic glucose production or an increased rate of glucose use. Symptoms suggestive of hypoglycemia are fairly common, but hypoglycemic disorders are rare. However, true hypoglycemia usually indicates serious underlying disease and may be life threatening. A precise threshold for establishing hypoglycemia is not always possible, and values as low as 30 mg/dL may be encountered in healthy premenopausal women after a 72-hour fast.[186] Symptoms usually begin at plasma glucose concentrations below 55 mg/dL, and impairment of cerebral function begins when glucose is less than 50 mg/dL.

The *classic diagnostic test is the 72-hour fast,* which should be conducted in a hospital.[255] During the fast, the patient should be allowed a liberal intake of calorie-free and caffeine-free fluids. All nonessential medications should be discontinued and patients should be active when awake. Samples should be drawn for analysis of plasma glucose, insulin, C-peptide, and proinsulin every 6 hours. When plasma glucose concentration is less than or equal to 60 mg/dL, analysis should be performed every 1 to 2 hours. The fast should be concluded when plasma glucose concentration falls to less than or equal to 45 mg/dL and the patient exhibits signs or symptoms of hypoglycemia. If this does not occur, the fast should be terminated after 72 hours. At the conclusion of the fast, draw blood for glucose, insulin, C-peptide, proinsulin, β-hydroxybutyrate, and sulfonylurea analysis. Then inject 1 mg of glucagon intravenously and measure plasma glucose concentration at 10, 20, and 30 minutes. This concludes the protocol and the patient can be fed. When a deficiency is suspected, plasma cortisol, growth hormone, or glucagon should be measured at the beginning and end of the fast. A gender difference is observed in plasma

glucose concentrations during prolonged fasting, with women exhibiting significantly lower concentrations than men. Low plasma glucose alone is not sufficient to establish the diagnosis, and the absence of signs or symptoms of hypoglycemia during the fast excludes the diagnosis of a hypoglycemic disorder.

More than 100 causes of hypoglycemia have been reported. Some of the more common conditions to be considered are listed in Box 25-5. Drugs are the most prevalent cause,[254] and a wide variety, including propranolol, salicylates, and disopyramide, can produce hypoglycemia. Oral hypoglycemic agents, which have a long half-life (35 hours for chlorpropamide), are the most frequent cause of drug-induced hypoglycemia. Sulfonylureas stimulate secretion of insulin, proinsulin, and C-peptide, and may mimic an insulinoma. Differentiation is made by demonstrating the drug in blood or urine. Surreptitious administration of insulin can be detected by finding low C-peptide concentrations with increased insulin concentrations.

Ethanol produces hypoglycemia by inhibiting gluconeogenesis, and this is aggravated by malnutrition (low glycogen stores) in patients with chronic alcoholism. The decreased glucose production in *hepatic failure* (e.g., viral hepatitis, toxins) caused by impaired gluconeogenesis or glycogen storage may result in hypoglycemia. Because this requires dysfunction of more than 80% of the liver, evidence of liver disease is invariably present. Deficiency of *growth hormone* (especially with coexistent ACTH deficiency), glucocorticoids, thyroid hormone, or glucagon may also produce hypoglycemia. Although a deficiency of glucocorticoids (e.g., Addison's disease) is most consistently associated with hypoglycemia, most glucocorticoid-deficient adults are not hypoglycemic. Hormonal deficiency causes hypoglycemia in children more frequently than in adults.

Demonstration of a low plasma glucose concentration in the presence of an abnormally high plasma insulin value is highly suggestive of an insulin-producing *pancreatic islet cell tumor.*[89] Because insulin concentrations exhibit a wide range in normal people, absolute hyperinsulinemia occurs in fewer than 50% of patients with insulinomas. Serum insulin concentrations inappropriately high for concurrent plasma glucose have been proposed to increase diagnostic accuracy. A plasma glucose concentration less than 30 mg/dL with a plasma insulin concentration exceeding 15 μIU/mL, insulin/glucose ratio greater than 0.3, or amended insulin/glucose ratio may be used. However, these ratios have unacceptably low sensitivity. C-peptide concentrations greater than or equal to 0.2 nmol/L at the end of a fast when plasma glucose was less than or equal to 50 mg/dL correctly identified all insulinoma patients. Provocative tests (glucagons,[163] tolbutamide,[256] calcium,[145] or suppression tests [infusion of insulin and measuring C-peptide]), although strongly recommended in the past, are generally not necessary. Intraarterial calcium stimulation with right hepatic vein sampling for insulin gradients appears to be a sensitive preoperative test for localizing insulinoma.[82]

Spontaneous production of *antibodies to insulin* may produce hypoglycemia (these antibodies are distinct from those elicited by insulin therapy and the antibodies detected in certain patients with type 1 diabetes). Antiinsulin antibodies causing hypoglycemia have been reported in Graves' disease, multiple myeloma, systemic lupus erythematosus, and rheumatoid arthritis. Patients exhibit postprandial hyperglycemia and fasting hypoglycemia. Laboratory analysis demonstrates low plasma C-peptide and high plasma insulin concentrations. It is important to test for antibodies to insulin because these may interfere with insulin immunoassays.

Nonpancreatic neoplasms that cause hypoglycemia are often extremely large mesenchymal neoplasms that appear to overuse glucose but may also have an inhibitory effect on glucose mobilization. Tumors of epithelial origin may cause hypoglycemia, frequently by producing IGF II.[70,257]

Hypoglycemia caused by *septicemia* should be relatively easy to diagnose.[188] The mechanism is not well defined, but depleted glycogen stores, impaired gluconeogenesis, and increased peripheral use of glucose may all be contributing factors. Glucose tolerance is commonly depressed in renal disease, and hypoglycemia may occur in end-stage *renal failure.*

Some of the conditions producing fasting hypoglycemia are readily apparent, but others require a lengthy diagnostic workup. Once hypoglycemia is demonstrated, specific tests should be performed to establish the underlying cause. The *OGTT is not an appropriate study for evaluating a patient suspected of having hypoglycemia.*

Postprandial Hypoglycemia

A group of disorders may produce hypoglycemia in the postprandial (fed) state.[124] These include drugs, antibodies to insulin or the insulin receptor, and inborn errors (e.g., fructose-1,6-diphosphatase deficiency). Also included is *reactive hypoglycemia* (also referred to as functional hypoglycemia), which has been the subject of much debate.[45] Many commentaries and editorials have been published regarding the existence of reactive hypoglycemia (Hofeldt[124] and references listed therein). The general consensus is that there is no scientific evidence that supports the existence of "functional hypoglycemia." It has been proposed that for individuals with vague symptoms after food ingestion the preferred terminology should be *idiopathic reactive hypoglycemia*[124] or *idiopathic postprandial syndrome.*[255]

At the Third International Symposium on Hypoglycemia,[169] reactive hypoglycemia was defined as a *clinical disorder in which the patient has postprandial symptoms suggesting hypoglycemia that occur in everyday life and are accompanied by a blood glucose concentration less than 45 to 50 mg/dL as determined by a specific glucose measurement on arterialized venous or capillary blood, respectively.* Patients complain of autonomic symptoms occurring approximately 1 to 3 hours after eating and seem to obtain relief, lasting 30

to 45 minutes, by food intake. These symptoms are rarely due to low blood glucose concentrations (e.g., diabetes mellitus, gastrointestinal dysfunction, or hormonal deficiency states). Most of these individuals have postprandial autonomic symptoms without neuroglycopenia in the postprandial state. Some experts in the field state that there are no true hypoglycemic disorders characterized solely by autonomic symptoms.[255] A 5- or 6-hour glucose tolerance test was the standard procedure to establish the presence of postprandial hypoglycemia, but has been discredited.[45] The test is not reproducible in any particular individual, and low values for plasma glucose may be noted in the absence of symptoms, whereas symptoms may occur with normal glucose concentrations.[56] In addition, patients who have low blood glucose concentrations with autonomic symptoms 3 or 4 hours after an oral glucose load may have identical symptoms with normal blood glucose values after a mixed meal.[56] This may be partly due to anxiety provoked by the stressful environment during the glucose tolerance test. Demonstration of increased plasma epinephrine concentrations at the glucose nadir during an OGTT was reported to differentiate patients with reactive hypoglycemia,[53] but the patients studied were identified on the basis of autonomic symptoms and signs, and only 25% demonstrated hypoglycemia. The *OGTT should not be used in the diagnosis of reactive hypoglycemia.*

Postprandial hypoglycemia is infrequent and the demonstration of hypoglycemia during spontaneously occurring symptomatic episodes is necessary to establish the diagnosis.[215] If this is not possible, a 5-hour meal tolerance test[56] (which simulates the composition of a normal diet) or a "hyperglucidic" (high glucose) breakfast test[45] has been proposed.

A diagnosis of hypoglycemia has also been used to explain a wide variety of disorders that appear unrelated to blood glucose abnormalities.[51] These nonspecific symptoms include fatigue, muscle spasms, palpitations, numbness, tingling, pain, sweating, mental dullness, sleepiness, weakness, and fainting. Behavior abnormalities, poor school performance, and delinquency have been incorrectly attributed to low blood glucose concentrations. The widespread use of the insensitive and nonspecific 5-hour glucose tolerance test caused overdiagnosis of hypoglycemia and led the ADA to publish a statement to discourage the inappropriate use of the OGTT for the diagnosis of hypoglycemia.[261] Lay publications[273] have supported this recommendation, but it is still important for the medical community to reassure such patients that low blood glucose is not the cause of their symptoms and to deal with specific abnormalities that might underlie patients' complaints or problems. A diagnosis of hypoglycemia should not be made unless a patient meets the criteria of *Whipple's triad of low blood glucose concentration with typical symptoms alleviated by glucose administration.* Demonstration of a normal plasma glucose concentration when the subject exhibits symptoms excludes the possibility of a hypoglycemic disorder.

Hypoglycemia in Diabetes Mellitus

Hypoglycemia occurs frequently in both type 1 diabetes and type 2 diabetes.[68,99] Patients using insulin experience approximately one to two episodes of symptomatic hypoglycemia per week, and severe hypoglycemia (i.e., requiring assistance from others or associated with loss of consciousness) affects about 10% of this population per year. In patients practicing intensive insulin therapy (e.g., multiple injections or continuous subcutaneous insulin infusion), these figures are increased twofold to sixfold. The chief adverse event associated with intensive therapy in the DCCT was a threefold increase in the incidence of severe hypoglycemia.[72] Similarly, hypoglycemia occurs in patients with type 2 diabetes (caused by oral hypoglycemic agents or insulin), but is less frequent than in type 1 diabetes. Two pathophysiological mechanisms contribute to hypoglycemia in patients with diabetes.

Defective Glucose Counterregulation

Counterregulatory responses become impaired in type 1 diabetes patients,[68] increasing the risk of hypoglycemia. The response of glucagon to hypoglycemia is impaired by an unknown mechanism early in the course of type 1 diabetes. Epinephrine secretory response to hypoglycemia becomes deficient later in the course of the disease. These defects are selective because other stimuli continue to elicit glucagon and epinephrine secretion. Glucose counterregulation does not appear to be notably defective in patients with type 2 diabetes.

Hypoglycemia Unawareness

Up to 50% of patients with long-standing (more than 30 years) type 1 diabetes do not experience neurogenic warning symptoms and are prone to more severe hypoglycemia. The mechanism is thought to be associated with a decreased epinephrine response to hypoglycemia. Intensively treated patients with type 1 diabetes require lower plasma glucose concentrations to elicit symptoms of hypoglycemia. Some authors have claimed that human insulin results in an increased incidence of hypoglycemia unawareness, but analysis of 45 studies revealed no significant differences in hypoglycemic episodes between insulin species.[234]

Tolbutamide Tolerance Test

Tolbutamide, 1-butyl-3-(*p*-tolylsulfonyl)urea *(Orinase),* stimulates the normal pancreas to produce insulin. The response of the pancreas to intravenous tolbutamide can be used in the investigation of fasting hypoglycemia. Blood specimens are obtained for glucose and insulin before intravenous injection of 1 g of a water-soluble form of tolbutamide and at 2, 15, 30, 60, 90, and 120 minutes afterward. Normal people have a decrease in plasma glucose concentration to about 50% of the fasting value by 30 minutes, with a return to baseline at 120 minutes. Patients with fasting hypoglycemia exhibit a lower glucose nadir, with hypoglycemia persisting up to 2 hours. The insulin response

CV, Coefficient of variation for all results by all methods of the indicated method-type from all manufacturers. It may include a component of variation attributable to differences in calibrators and to matrix effects.

*Results are based on 2003 CAP Survey, Set C-A, Specimen C-11 (Copyright, 2003 College of American Pathologists; data used with permission). See text for discussion of methods.

†"Number" and numbers in parentheses indicate how many laboratories use the indicated method-type.

provides further diagnostic information. The peak insulin concentration at 2 minutes is normally less than 150 μIU/mL. This value is increased in patients with islet cell tumors, and the elevated insulin concentration at 60 minutes is reported to be the most reliable discriminator.[36] In various conditions—such as liver disease, malnutrition, or renal insufficiency—plasma glucose responses to tolbutamide are indistinguishable from those seen with islet cell tumors, *but only patients with insulinoma exhibit exaggerated plasma insulin concentrations.*

The test has also been proposed for the diagnosis of diabetes mellitus. If the blood glucose concentration at 20 minutes is between 80% and 84% of the fasting value, the patient is said to have a 50% probability of having diabetes. In some severe cases, the response is even less because the pancreas is unable to secrete adequate amounts of insulin. However, *this test has no role in the diagnosis of diabetes.* Patients must be carefully observed for hypoglycemic reactions, and the test terminated, if necessary, by intravenous administration of glucose. This test is potentially dangerous and should not be performed in people with moderate or severe fasting hypoglycemia. The tolbutamide test should not be administered if the plasma glucose concentration is less than 60 mg/dL immediately before the test.

DETERMINATION OF GLUCOSE IN BODY FLUIDS

Many analytical procedures are used to measure blood glucose concentrations. In the past, analyses were often performed with relatively nonspecific methods that resulted in falsely increased values. Almost all commonly used techniques are now enzymatic (e.g., hexokinase or glucose oxidase), and older methods, such as photometric or oxidation-reduction techniques, are rarely used. The glucose assays most widely used in the United States may be determined by inspecting quality control surveys conducted by the College of American Pathologists (CAP). Results from 5409 laboratories reported in a survey conducted in 2003 are displayed in Table 25-5. These data show that automated hexokinase methods are used in half of the participating laboratories. The extensive use of the hexokinase method is a reflection of the procedures adopted by the manufacturers of automated equipment. Glucose oxidase is the only other method that is widely used. The most significant change in the past 20 years is the disappearance of the *o*-toluidine method, which was used in the SMA 12/60 Autoanalyzer. It must be emphasized that these data apply only to this CAP survey and are weighted to laboratories participating either on a voluntary basis or in compliance with state regulatory agencies. Many kits are commercially available for measuring glucose and are widely used, especially in smaller laboratories. Furthermore, testing performed in physicians' offices is not included. Reference to CAP surveys demonstrates that all the methods exhibit a CV less than 5% for glucose values on lyophilized serum, with automated methods having CVs less than or equal to 2.6%.

Methods for the determination of glucose in blood have been reviewed,[48] and 10 glucose methods have been evaluated and compared with a generally accepted hexokinase reference method.[217]

Specimen Collection and Storage

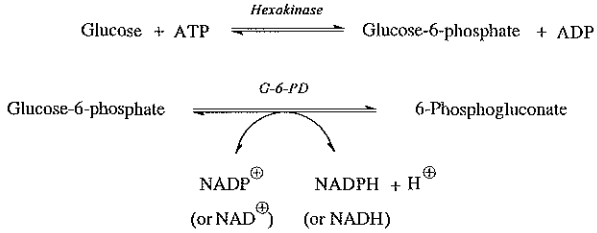
In individuals with a normal hematocrit, fasting whole-blood glucose concentration is approximately 10% to 12% lower than plasma glucose. Although the glucose concentra-

tions in the water phase of red blood cells and plasma are similar (the erythrocyte plasma membrane is freely permeable to glucose), the water content of plasma (93%) is approximately 11% higher than that of whole blood. In most clinical laboratories, plasma or serum is used for most glucose determinations; methods for self-monitoring of glucose use whole blood samples but may measure the glucose concentration in the plasma phase. During fasting, capillary blood glucose concentration is only 2 to 5 mg/dL higher than that of venous blood. After a glucose load, however, capillary blood glucose concentrations are 20 to 70 mg/dL ([mean ~ 30 mg/dL], equivalent to 20% to 25%) higher than concurrently drawn venous blood samples.[166]

Glycolysis decreases serum glucose by approximately 5% to 7% in 1 hour (5 to 10 mg/dL) in normal uncentrifuged coagulated blood at room temperature.[54,287] The rate of in vitro glycolysis is higher in the presence of leukocytosis or bacterial contamination. Other workers have observed a decrease of only 1.9 mg/dL/hr when blood was drawn into sterile Vacutainer-brand tubes.[247] This negligible decrease can be attributed in part to prevention of bacterial contamination and to lower ambient temperatures. In separated, *nonhemolyzed sterile serum, the glucose concentration is* generally stable as long as 8 hours at 25 °C and up to 72 hours at 4 °C; variable stability is observed with longer storage periods.[40] Plasma, removed from the cells after moderate centrifugation, contains leukocytes that also metabolize glucose—although cell-free sterile plasma has no glycolytic activity.

Glycolysis can be inhibited and glucose stabilized for as long as 3 days at room temperature by adding sodium fluoride (NaF), or less commonly, sodium iodoacetate to the specimen.[78] Fluoride ions prevent glycolysis by inhibiting enolase, an enzyme that requires Mg^{2+}. The inhibition is due to the formation of an ionic complex consisting of Mg^{2+}, inorganic phosphate, and fluoride ions; this complex interferes with the interaction of enzyme and substrate. Fluoride is also a weak anticoagulant because it binds calcium; however, clotting may occur after several hours, and it is therefore advisable to use a *combined fluoride-oxalate mixture,* such as 2 mg of potassium oxalate ($K_2C_2O_4$) and 2 mg of NaF/mL of blood, to prevent late clotting. Other anticoagulants (e.g., EDTA, citrate, or heparin) can also be used. Fluoride ions in high concentration inhibit the activity of urease and certain other enzymes; consequently the specimens are unsuitable for determination of urea in procedures that require urease and for direct assay of some serum enzymes. $K_2C_2O_4$ causes a loss of cell water, thereby diluting the plasma. Samples collected in these tubes should therefore not be used for measurement of other analytes. *Although fluoride maintains long-term blood glucose stability,* the rate of decline in the first hour after sample collection is not altered.[54] It is probably not necessary in routine analysis to use a fluoride-containing tube if plasma is separated from cells or if glucose is measured within 60 minutes of blood collection. However, inhibitors of glycolysis are necessary in patients with greatly increased leukocyte counts because differences of up to 65 mg/dL have been observed between glucose values with and without glycolytic inhibitors after 1 to 2 hours of contact with the blood cells.

Cerebrospinal fluid (CSF) may be contaminated with bacteria or other cells and should be analyzed for glucose immediately. If a delay in measurement is unavoidable, the sample should be centrifuged and stored at 4 °C or −20 °C.



In 24-hour collections of urine, glucose may be preserved by adding 5 mL of glacial acetic acid to the container before starting the collection. The final pH of the urine is usually between 4 and 5, which inhibits bacterial activity. Other preservatives that have been proposed include 5 g of sodium benzoate per 24-hour specimen or chlorhexidine and 0.1% sodium nitrate (NaN_3) with 0.01% benzethonium chloride. These may be inadequate, and urine should be stored at 4 °C during collection. Urine samples may lose as much as 40% of their glucose after 24 hours at room temperature.[173]

Methods

Hexokinase and glucose oxidase are the two main types of methods used to measure glucose in body fluids. Other methods are found on the Evolve site that accompanies this book.

Hexokinase Methods

Glucose is phosphorylated by ATP in the presence of hexokinase and Mg^{2+}. The glucose-6-phosphate formed is oxidized by glucose-6-phosphate dehydrogenase (G6PD) to 6-phosphogluconate in the presence of nicotinamide-adenine dinucleotide phosphate (NADP+). The amount of NADPH produced is directly proportional to the amount of glucose in the sample and is measured by absorbance at 340 nm. G6PD derived from yeast is used in the assay with $NADP^+$ as the cofactor. The oxidized form of nicotinamide-adenine dinucleotide (NAD^+) is the cofactor if bacterial (*Leuconostoc mesenteroides*) G6PD is used, and the NADH produced is also measured at 340 nm.

A generally accepted reference method based on this principle has been developed and validated.[206] Serum or plasma is deproteinated by adding solutions of barium hydroxide ($Ba[OH]_2$) and zinc sulfate ($ZnSO_4$). The clear supernatant is mixed with a reagent containing ATP, NAD^+, hexokinase, and G6PD, incubated at 25 °C until the reaction is complete, and NADH measured. Calibrators and blanks are carried through the entire procedure, including the deproteination

step. Detailed specifications are given for the equipment, materials, and reagents, including tests of enzyme reagent adequacy.

Although highly accurate and precise, the reference method is too exacting and time consuming for routine use in a clinical laboratory. An alternative approach is to apply the reaction directly to serum or plasma and use a specimen blank to correct for interfering substances that absorb at 340 nm.[205] Because almost all methods are automated and rely on commercially prepared reagents supplied in lyophilized form, only a general discussion of the procedure is presented here.

Either serum or plasma may be used. NaF, with an anticoagulant such as EDTA, heparin, oxalate, or citrate, may be used. Hemolyzed specimens containing more than 0.5 g hemoglobin/dL are unsatisfactory because phosphate esters and enzymes released from red blood cells interfere with the assay. Other sources of interference include drugs, bilirubin, and lipemia (triglyceride greater than or equal to 500 mg/dL causes a positive interference). A sample blank is therefore recommended for lipemic and icteric samples. This blank is prepared by adding 10 µL of sample to isotonic saline or buffer instead of reagent. The absorbance of this mixture, read against water at 340 nm, is subtracted. Although fructose interferes in the assay, normal fasting serum has low fructose concentrations. After ingestion of sucrose 2 g/kg of body weight, serum fructose concentration increases up to 8 to 10 mg/dL within 1 hour and persists for 2 hours. Solutions administered during glucose tolerance testing should therefore not contain any fructose.

Absorbances of sample or calibrator reaction mixtures are measured after the reactions have continued to completion (equilibrium reaction). Although glucose concentrations may be calculated directly, based on the molar absorptivity of NADPH or NADH, inclusion of a set of calibrators is recommended to detect possible deterioration of enzymes, ATP, $NADP^+$, or NAD^+, all of which are unstable. Reagents may also contain substances that react with the coenzymes. Presence of these substances can be evaluated by measuring the increase in absorbance observed in a reagent blank. Reagents are unsuitable for use if the absorbance at 340 nm exceeds 0.35, using water as the blank. The highest calibrator provides a check on the linearity of response and the adequacy of the enzyme reagent. The procedure is linear from 0 to 500 mg/dL. Glucose concentrations that exceed 500 mg/dL should be diluted with isotonic saline and reassayed.

Hexokinase procedures in which indicator reactions produce colored products are also available, enabling absorbance to be measured in the visible range.[299] An oxidation-reduction system containing phenazine methosulfate (PMS) and a substituted tetrazolium compound, 2-(*p*-iodophenyl)-3-*p*-nitrophenyl-5-phenyltetrazolium chloride (INT), is reacted with NADPH formed in the reaction. The reduced INT is colored with maximum absorbance at 520 nm. The PMS-INT color developer must be refrigerated when not in use and must be protected from exposure to light to retard autoreduction.

Glucose Oxidase Methods

The enzyme glucose oxidase catalyzes the oxidation of glucose to gluconic acid and hydrogen peroxide (H_2O_2):

$$\text{Glucose} + 2H_2O + O_2 \xrightarrow{\text{Glucose Oxidase}} \text{Gluconic acid} + 2H_2O_2$$

Addition of the enzyme peroxidase and a chromogenic oxygen acceptor, such as *o*-dianisidine, results in the formation of a colored compound that can be measured:

$$\underset{\text{(Colorless)}}{\text{o-Dianisidine}} + H_2O_2 \xrightarrow{\text{Peroxidase}} \underset{\text{(Colored)}}{\text{Oxidized } o\text{-Dianisidine}} + H_2O_2$$

Glucose oxidase is highly specific for β-D-*glucose.* As noted earlier, 36% and 64% of glucose in solution are in the α- and β-forms, respectively. Complete reaction of glucose therefore requires mutarotation of the α- to β-form. Some commercial preparations of glucose oxidase contain an enzyme—mutarotase—that accelerates this reaction. Otherwise, extended incubation time allows spontaneous conversion.

The second step, involving peroxidase, *is much less specific than the glucose oxidase reaction.* Various substances, such as uric acid, ascorbic acid, bilirubin, hemoglobin, tetracycline, and glutathione, inhibit the reaction (presumably by competing with the chromogen for H_2O_2), producing lower values. Incorporation of potassium ferrocyanide significantly decreases interference by bilirubin. Most interfering substances can be eliminated by use of a Somogyi filtrate (see the discussion under oxidation reduction methods on the Evolve site that accompanies this book at http://evolve.elsevier.com/Tietz/textbook). Acid filtrates cannot be used because peroxides, which cause falsely elevated results, may be released. Most modern methods omit the preparation of protein-free filtrates to make the procedure faster and simpler. Some glucose oxidase preparations contain catalase as a contaminant; catalase activity decomposes peroxide and decreases the final color obtained. Calibrators and unknowns should be analyzed simultaneously under conditions in which the rate of oxidation is proportional to glucose concentration.

In some methods, the final mixture is acidified slightly to stop the reaction, and the intensity of the yellow chromophore is measured at 400 nm. In stronger acid solution, the color becomes pink, with maximum absorbance at 540 nm, and both sensitivity and stability are improved. Other approaches to measurement of the H_2O_2 produced include the peroxide-mediated oxidative coupling of 3-methyl-2-benzothiazolinone hydrazone (MBTH) with *N,N*-dimethyl-aniline (DMA) catalyzed by peroxidase[106] or the oxidative coupling of *p*-aminophenazone (PAP) to phenol.[278] Both procedures have been automated. The

MBTH-DMA and PAP procedures are not affected by high concentrations of creatinine, uric acid, or hemoglobin and are performed directly on serum. The chromogen 2-amino-4-hydroxybenzenesulfonic acid produces a yellow color in the presence of peroxidase and H_2O_2.[231] Additional components are not required to produce the color and the assay can be performed on as little as 2 µL of serum.

Glucose oxidase methods are *suitable for measuring glucose in CSF.* Urine contains high concentrations of substances that interfere with the peroxidase reaction (such as uric acid), producing falsely low results. The glucose oxidase method should therefore *not be used for urine.* A method in which the urine is first pretreated with an ion-exchange resin to remove interfering substances has been described.

Modified Glucose Oxidase Methods

Some instruments use a polarographic oxygen electrode that measures the rate of oxygen consumption after the sample is added to a solution containing glucose oxidase.[143] Because this measurement involves only the first reaction shown earlier, *interferences encountered in the peroxidase step are eliminated.* To prevent formation of oxygen from H_2O_2 by catalase present in some preparations of glucose oxidase, H_2O_2 is removed by two additional reactions:

$$H_2O_2 + C_2H_5OH \xrightarrow{\text{Catalase}} CH_3CHO + 2H_2O$$

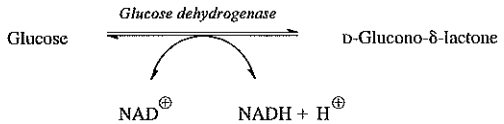
$$H_2O_2 + 2H^+ + 2I^- \xrightarrow{\text{Molybdate}} I_2 + 2H_2O$$

The latter reaction is effective even when catalase activity has diminished on storage of reagents. The procedure can be applied directly to *urine, serum, plasma,* or *CSF.* However, this approach cannot be used for the *determination of glucose in whole blood* because blood cells consume oxygen.

In the YSI Model 23A (Yellow Springs Instrument Co., Yellow Springs, Ohio), glucose oxidase is immobilized in a thin layer of resinous material sandwiched between two membranes. When a buffered sample is introduced, glucose diffuses through the first polycarbonate membrane and reacts with the enzyme to produce H_2O_2. This diffuses through the second, smaller pore cellulose acetate membrane and is oxidized at a platinum anode. The current generated is directly proportional to the glucose concentration in the diluted sample.

$$H_2O_2 \rightarrow 2H^+ + O_2 + 2e^-$$

The circuit is completed at a silver cathode, where oxygen is reduced to water.



$$4H^+ + O_2 + 4e^- \rightarrow 2H_2O$$

Any H_2O_2 diffusing back into the sample chamber is destroyed by catalase to prevent interference with the analysis. Determinations may be performed on 25 µL of *plasma, serum,* or *whole blood.* Good precision and correlation with an oxygen consumption rate analyzer have been reported.[59]

The Vitros system (Ortho-Clinical Diagnostics, Raritan, NJ) makes use of dry multilayer films for chemical analyses.[69] Glucose is measured by a glucose oxidase procedure. A 10-µL sample of *serum, plasma, urine, or CSF* is placed on a porous film on top of the layer containing the reagents. Glucose diffuses through the film and reacts with the reagents to produce a colored end product or dye. The intensity of this dye is measured through a lower transparent film by reflectance spectrophotometry. Advantages of this system include small sample size, no liquid reagents, and improved stability on storage.

Glucose Dehydrogenase Methods

The enzyme glucose dehydrogenase (β-D-glucose : NAD oxidoreductase, EC 1.1.1.47) catalyzes the oxidation of glucose to gluconolactone. Mutarotase is added to shorten the time necessary to reach equilibrium. The amount of NADH generated is proportional to the glucose concentration:

Glucose dehydrogenase for this assay is isolated from *Bacillus cereus.* The reaction appears to be highly specific for glucose, shows no interference from common anticoagulants and substances normally found in serum, and provides results in close agreement with hexokinase procedures. Methods have been adapted to continuous-flow analyzers,[49] including the use of immobilized enzyme,[265] and to a centrifugal analyzer.[176]

Reference Intervals

Although glucose can be assayed by several different analytical procedures, reference intervals do not vary significantly among methods. The following values should apply to virtually all currently used glucose assays.

	Sample Fasting Glucose (mg/dL)
Plasma/serum	
Adults	74-106 (4.5-5.9 mmol/L)
Children	60-100 (3.5-5.6 mmol/L)
Premature neonates	20-60 (1.1-3.3 mmol/L)
Term neonates	30-60 (1.7-3.3 mmol/L)
Whole blood	65-95 (3.5-5.3 mmol/L)
CSF	40-70 (2.2-3.9 mmol/L) (60% of plasma value)
Urine	
24 hr	1-15 mg/dL (0.1-0.8 mmol/L)

Note that the ADA criteria,[7] not the reference interval, are used for the diagnosis of diabetes. Moreover, the threshold for diagnosis of hypoglycemia is variable and is considerably

less than the lower limit of the reference interval. There is no sex difference. *Plasma glucose values increase with age from the third to the sixth decade:* fasting, approximately 2 mg/dL per decade; postprandial, 4 mg/dL per decade; and after a glucose challenge, 8 to 13 mg/dL per decade.[212] Fasting plasma glucose does not increase significantly after age 60, but glucose concentrations after a glucose challenge are substantially higher in older individuals.[75] Evidence of an association of increasing insulin resistance with age is inconsistent.[137,241]

CSF glucose concentrations should be approximately 60% of the plasma concentrations and *must always be compared with concurrently measured plasma glucose* for adequate clinical interpretation.

Measurement of Glucose in Urine

Examination of urine for glucose is rapid, inexpensive, and noninvasive and can be used to screen large numbers of samples. The older screening tests detect sugars that reduce copper, producing a color.[128] These react with reducing substances other than glucose (Box 25-6). Qualitative, semiquantitative, and quantitative methods are available for measuring glucose in urine and have essentially replaced the nonspecific tests in adults. *Note:* A reducing sugar method, rather than an enzymatic method specific for glucose, must be used when screening neonates and infants for inborn errors of metabolism that result in the appearance of reducing sugars other than glucose (e.g., galactose or fructose) in the urine.

Qualitative Method

In one such method (details of which are found on the Evolve site that accompanies this book), using "Benedict's" reagent (cupric ion complexed to citrate in alkaline solution), reducing substances convert cupric to cuprous ions, forming yellow cuprous hydroxide or red cuprous oxide.

Semiquantitative Methods

Convenient paper test strips are commercially available from a number of manufacturers (Clinistix and Diastix, Bayer Corp., and Chemstrip μG, Roche Diagnostics, Indianapolis).

BOX 25-6 Reducing Substances in Urine

Fructose	Ketone bodies
Lactose	Sulfanilamide
Galactose	Oxalic acid
Maltose	Hippuric acid
Arabinose	Homogentisic acid
Xylose	Glucuronic acid
Ribose	Formaldehyde
Uric acid	Isoniazid
Ascorbic acid	Salicylates
Creatinine	Cinchophen
Cysteine	Salicyluric acid
Glucose	

All strips use the *glucose-specific enzyme glucose oxidase in a chromogenic assay.* For example, Clinistix has filter paper impregnated with glucose oxidase, peroxidase, and the dye o-tolidine. Other dyes, such as tetramethylbenzidine (TMB), can be used. The test end of the strip is moistened with freshly voided urine and examined after 10 seconds. A blue color develops if glucose is present at a concentration of 100 mg/dL or greater. Results are read by comparing the test color with a standard color chart. Automated urinalysis systems capable of analyzing 300 strips per hour are commercially available. The test is more sensitive for glucose than the copper reduction test (Clinitest), which has a detection limit of 250 mg/dL. Despite these claims, evaluation of dipsticks reveals high imprecision at low urine glucose concentrations.[95] Clinitest was reported to detect glucose only when it was above 1 g/L, and only Chemstrip μG could differentiate urine glucose at 300 mg/L (upper limit of reference interval) from 600 mg/L.[26] The sensitivity of the strip has been adjusted to take into account the presence of enzyme inhibitors normally present in urine. Thus a positive test result is obtained with lower concentrations of glucose in water than in urine. For the same reason, misleading high results may be obtained with very dilute specimens.

False-positive results may be produced by contamination of urine with H_2O_2 or a strong oxidizing agent, such as hypochlorite (bleach). Exposure of dipsticks to air gives false-positive readings after 7 days.[63] False-negative results may occur with large quantities of reducing substances, such as ketones, ascorbic acid, and salicylates. In one study of 2000 urine specimens, 11 false-negative enzyme paper tests were encountered. Among the inhibitors identified were ascorbic acid, dipyrone, and meralluride sodium (Mercuhydrin). Several antibiotics contain ascorbic acid as a preservative, which is excreted essentially unchanged. For routine examinations, a negative result by the strip test is usually interpreted to mean that the urine specimen is negative for glucose.

Other strip tests (Keto-Diastix, Bayer Corp., and Chemstrip μGK, Roche Diagnostics) are designed for the semiquantitative estimation of both glucose and ketone bodies. The glucose portion of the strip uses the glucose oxidase–peroxidase method. The hydrogen peroxide produced oxidizes iodide to iodine, yielding various intensities of brown that correspond to the concentration of glucose in the urine. The detection limit is 100 mg/dL. The Diastix and Chemstrip glucose tests are reported to be less inhibited by ascorbic acid than Clinistix.

Quantitative Methods

Applications of various procedures for quantitative determination of glucose in urine were discussed earlier in this chapter under Determination of Glucose in Body Fluids. The hexokinase or glucose dehydrogenase procedures are recommended for greatest accuracy and specificity. Glucose oxidase procedures that depend only on the consumption of oxygen or the production of H_2O_2 are also reliable. Glucose

oxidase procedures that include the H_2O_2-peroxidase reaction are not acceptable.

Self-Monitoring of Blood Glucose

Diabetic patients, especially those who need insulin therapy, require careful monitoring to maintain control of blood glucose. This has become particularly important with the results of the DCCT[72] and the recommendation that patients use intensive insulin therapy regimens to achieve nearly normal glycemia. These regimens include multiple daily insulin injections, insulin pumps, and continuous subcutaneous insulin injections. Estimating blood glucose concentrations by monitoring urine glucose concentrations, a simple and convenient method, is undesirable for the following reasons:

1. The renal threshold (the blood glucose concentration above which glucose appears in the urine) averages 160 to 180 mg/dL but varies widely among individuals. It may increase in long-standing diabetes or with age and may be lower in pregnancy or childhood. A decreased threshold (± 100 mg/dL) is known as *renal glycosuria.*
2. Monitoring of urine glucose concentrations lacks sensitivity and specificity. For example, one study demonstrated that patients with plasma glucose concentrations between 150 and 199 mg/dL exhibited normal urine test results 75% of the time. Furthermore, 9% of patients with plasma glucose concentrations below 149 mg/dL had glycosuria.[194]
3. A negative test result does not distinguish between hypoglycemia, euglycemia, and moderate hyperglycemia.
4. Urine testing is not accurate.
5. Other factors influence testing (e.g., fluid intake, urine concentration, ingestion of salicylates or ascorbic acid, and urinary tract infections).

Testing urine for glucose is therefore not adequate for monitoring patients on insulin therapy.[6] Although some evidence suggests that it may be effective for monitoring type 2 diabetes,[2] the ADA states that limitations of urine testing make blood glucose measurements the preferred method of assessing glycemic control.[108]

Glucose Meters

Portable meters for measurement of blood glucose concentrations are used in three major settings: (a) in acute and chronic care facilities (at the patient's bedside and in clinics or hospitals); (b) in physicians' offices; and (c) by patients at home, work, and school. The last, self-monitoring of blood glucose (SMBG), used by approximately 1 million diabetic patients, is performed in the United States at least once a day by 40% and 26% of individuals with type 1 and 2 diabetes, respectively.[241] The worldwide market for SMBG is $2.7 billion per year, with annual growth estimated at 10% to 12%.[241]

Patients measure their own blood glucose concentration and modify their insulin dose based on this glucose value. It is impractical for patients themselves to perform glucose determinations by the methods described earlier, but a large number of simple test strips that are available permit rapid and reasonably accurate measurements on a drop of whole blood.[65] These use the same methodology as described earlier for glucose analysis—predominantly glucose oxidase or hexokinase—but some strips contain glucose dehydrogenase. In many strips, a dye is colored by the glucose oxidase-peroxidase chromogenic reaction. The reagents are combined in dry form on a small surface area of a test strip, and the colors that develop may be evaluated visually by comparison with a color chart (rarely used any more) or quantified in a specially designed meter. *Visual reading with a color chart is not accurate enough* for most clinical circumstances. At least 25 different blood glucose meters are commercially available and these vary in size, weight, calibration method, and other features. These are reviewed annually in the ADA's Buyer's Guide to Diabetes Products.[11]

To perform the measurement, a sample of blood (usually from a fingerstick, but anticoagulated whole blood collected in EDTA or heparin may be used) is placed on the test pad, which is attached to a plastic support. The test strip is then inserted into the meter. (In some devices, the strip is inserted in the meter before applying the sample.) After a fixed period of time, the result appears on a digital display screen. The meters use reflectance photometry or electrochemistry to measure the rate of the reaction or the final concentration of the products. Reflectance photometry measures the amount of light reflected from a test pad containing reagent. In electrochemical systems, the enzymatic reaction in an electrode incorporated on the test strip produces a flow of electrons. The current, which is directly proportional to the amount of glucose in the sample, is converted to a digital readout. There is large variability among meters as to the test time (15 to 120 seconds) and the claimed reading range (40 to 400 mg/dL to 0 to 600 mg/dL). Calibration is automatic on some devices, whereas others use lot-specific code chips or strips. All manufacturers supply control solutions. Strict adherence to the instructions is necessary to obtain accurate results. Some meters have a porous membrane that separates erythrocytes, and analysis is performed on the resultant plasma. *Whole blood glucose concentrations are approximately 10% to 15% lower than plasma or serum concentrations, but meters can be calibrated to report plasma glucose values, even when the sample is whole blood.* An International Federation of Clinical Chemistry (IFCC) working group recently recommended that glucose meters be harmonized to report the concentration of glucose in plasma, irrespective of the sample type or technology.[47]

Analytical Goals

Multiple analytical goals have been proposed for the performance of glucose meters. The rationale for these is not always clear. In 1987 the ADA recommended a goal of total error (in the hands of users) of less than 10% at glucose concentrations of 30 to 400 mg/dL 100% of the time.[5] The

recommendation was modified in response to the significant reduction in complications by tight glucose control in the DCCT. The revised performance goal, published in 1996,[6] is for analytical error to be less than 5%. No published studies of glucose meters have achieved this goal. The Clinical Laboratory Improvement Amendment (CLIA) 88 goal is less stringent than that of the ADA; results with meters should be within 10% of target values or within 6 mg/dL, whichever is larger. The National Committee for Clinical Laboratory Standards (NCCLS) recommendations[202] are that results should fall within 20% of laboratory-measured glucose concentrations when greater than 75 mg/dL and within 15 mg/dL of laboratory glucose if the glucose concentration is less than or equal to 75 mg/dL.

A different method was proposed by Clarke,[62] who developed an error grid that attempts to define clinically important errors by identifying fairly broad target ranges. In addition, a novel approach using simulation modeling revealed that meters that achieve both a CV and a bias less than 5% rarely lead to major errors in insulin dose.[41] The lack of consensus on quality goals for glucose meters reflects the absence of agreed-upon objective criteria. Using biological variation criteria, a goal for total error (including both bias and imprecision) of less than or equal to 7.9% has been proposed.[241] However, additional studies are necessary to accurately define this goal.

Performance of Glucose Meters

The most common errors in SMBG, such as proper application, timing, and removal of excess blood, have been eliminated by advances in technology. Additional innovations that reduce operator error include systems that abort testing if the sample volume is inadequate, built-in programs that simplify quality control, and memory that allows the instrument to store up to several hundred glucose readings that can be downloaded into a computer.

Several factors affect the accuracy and reproducibility of SMBG. These include: (a) user variability—up to 50% of the values may vary more than 20% from the reference values[65]; (b) hematocrit—the presence of anemia (false increase) or polycythemia (false depression) may result in up to 30% variability; and (c) defective reagent strips or instrument malfunction (rare). Other variables include changes in altitude, environmental temperature, or humidity; hypotension; hypoxia; and high triglyceride concentrations. In addition, *these assays are unreliable at very high and very low glucose concentrations* (less than 60 and greater than 500 mg/dL). Because dehydration, a common feature of diabetic ketoacidosis, greatly increases blood viscosity, inaccurately low blood glucose results may be obtained. Several drugs interfere, but not with all meters.[269] Another important factor is the lack of correlation among meters, even from a single manufacturer, caused by different assay methods and architecture. In fact, results from two meters of the same brand have been observed to differ substantially.[270] The analytical performance characteristics of several meters have been published.[140,283] Patient factors are also important, particularly adequate training. Recurrent education at clinic visits and comparison of SMBG with concurrent laboratory glucose analysis improved the accuracy of patients' blood glucose readings.[142] In addition, it is important to evaluate the patient's technique at regular intervals.

The performance of different meters varies widely. Although current meters, as predicted, exhibit performance superior to prior generations of meters,[288] imprecision remains high. Under carefully controlled conditions in which all assays were performed by a single medical technologist, ~50% of analyses met the ADA criterion of less than 5% deviation from reference values.[288] Performance of older meters was substantially worse. Note that the performance of glucose meters achieved by medical technologists is better than that achieved by patients. Another study that evaluated meter performance in 226 hospitals by split samples analyzed simultaneously on meters and laboratory glucose analyzers revealed that 45.6%, 25%, and 14% differed from each other by greater than 10%, greater than 15%, and greater than 20%, respectively.[208] Recent comparison with laboratory values of almost 22,000 measurements of capillary glucose by patients using meters revealed no significant improvement in meter performance between 1989 and 1999.[37]

Indications and Frequency of SMBG

The indications and frequency of self-monitoring vary among patients. *SMBG should be performed by all patients treated with insulin.* The role of SMBG in patients with type 2 diabetes has not been defined.[241] A consensus statement by the ADA[65] recommended the following specific indications for SMBG: (1) patients undergoing intensive insulin treatment programs (in this group, glucose should be measured at least four times a day to achieve glycemic control); (2) preventing and detecting hypoglycemia, especially in people who are asymptomatic or unable to recognize the early warning signs; (3) avoidance of severe hyperglycemia, particularly in situations of increased risk (e.g., medications that alter insulin secretion or action, intercurrent illness, and elderly people); (4) adjusting pharmacological therapy in response to changes in life-style, such as exercise or altering food intake; and (5) determining the necessity for initiating insulin therapy in GDM. *SMBG must not be used to diagnose diabetes mellitus,* and its role in screening remains uncertain.[241]

SMBG should be performed at least four times per day in patients with type 1 diabetes. Monitoring less frequently than four times a day results in a deterioration of glycemic control.[6,199,248] Published studies reveal that self-monitoring is performed by patients much less frequently than recommended: at least once a day by 39% of patients taking insulin and 5% to 6% of those treated with oral agents or diet alone.[116] Moreover, 29% and 65% of patients treated with insulin and oral agents, respectively, monitored their blood glucose less than once per month. However, no evaluation

has been performed to verify that four times a day is ideal or whether some other frequency or timing (e.g., postprandial testing) would improve glycemic control. The optimum frequency of SMBG for patients with type 2 diabetes is unknown. Published evidence shows no correlation between the frequency of SMBG in type 2 diabetes and glycemic control.[67,88,116] There is no known role for SMBG in patients with type 2 diabetes who are treated with diet alone.

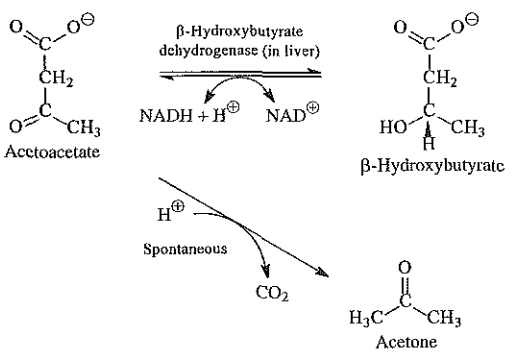
Minimally Invasive Monitoring of Blood Glucose

Fewer than 10% of patients with diabetes routinely perform SMBG because it is painful and inconvenient. Since the 1960s, attempts have been made to develop a painless method for monitoring blood glucose concentrations. Three general approaches have been used, namely implanted sensors, minimally invasive monitoring, and noninvasive monitoring.

Implanted Sensors

Several implanted biosensors have been developed and evaluated in both animals and humans (see Chapter 4). Detection systems are based on enzymes, electrodes, or fluorescence.[149,221] The most widely studied method is an electrochemical sensor that uses glucose oxidase.[295] This sensor can be implanted intravenously or subcutaneously. Intravenous implantation in dogs for up to 3 months has demonstrated the feasibility of this approach.[111] Alternatives to enzymes are being developed, including artificial glucose "receptors." Less success has been achieved with subcutaneous implants. Implantation of a needle type of sensor into the subcutaneous tissue induces a host of inflammatory responses that alters the sensitivity of the device. Microdialysis with hollow fibers or ultrafiltration with biologically inert material can decrease this problem.

Minimally Invasive Glucose Monitoring



The concept underlying these methods is that the concentration of glucose in the interstitial fluid correlates with blood glucose concentration. The principle of the Food and Drug Administration (FDA)–approved Gluco Watch (Cygnus) is the application of a low-level electric current on the skin. This induces movement by electroosmosis of glucose across the skin where it is measured by a glucose oxidase detector.[97,268] Glucose concentrations in transdermal fluid and plasma are highly correlated. The clearest application of the Gluco Watch, which is designed to measure glucose three times per hour for up to 12 hours, appears to be in the detection of unsuspected hypoglycemia. Calibration with reference plasma glucose is required. Initial clinical studies reveal reasonable correlation of the Gluco Watch with SMBG.[97,268] The device has not been rigorously tested in a home setting nor in children, but is likely to stimulate enhanced efforts to bring other technologies into clinical use.

Noninvasive Glucose Monitoring

Noninvasive in vivo monitoring of glucose is an area of active investigation. Near-infrared spectroscopic devices measure either the absorption or reflection of light from subcutaneous tissue. Although glucose has a specific absorption at 1035 nm, many substances interfere. A computer, individually calibrated, screens out interfering information to obtain the glucose result. Similar limitations have prevented successful use of light scattering. Photoacoustic spectroscopy, which uses pulsed infrared light, is a newer technique that shows some promise.

KETONE BODIES

The development of ketosis requires changes in both adipose tissue and the liver. *The primary substrates for ketone body formation are free fatty acids* from adipose stores. Normally, long-chain fatty acids are taken up by the liver, reesterified to triglycerides, and stored in the liver or incorporated in very-low-density lipoproteins and returned to the plasma. In contrast to other tissue, the brain cannot use free fatty acids for energy. When glucose is unavailable, ketone bodies supply the vast majority of the brain's energy. After a 3-day fast, ketone bodies provide 30% to 40% of the body's energy requirements.[165] In uncontrolled diabetes, the low insulin concentrations result in increased lipolysis and decreased reesterification, thereby increasing plasma free fatty acids. In addition, the increased glucagon : insulin ratio enhances fatty acid oxidation in the liver. Increased counterregulatory hormones also augment lipolysis and ketogenesis in fat and liver, respectively. Thus increased hepatic ketone production and decreased peripheral tissue metabolism lead to acetoacetate accumulation in the blood. A small fraction undergoes spontaneous decarboxylation to form acetone, but the majority is converted to β-hydroxybutyrate.

The relative proportions in which the three ketone bodies are present in blood vary depending on the redox state of the cell. In healthy people, β-hydroxybutyrate and acetoacetate—which are present at approximately equimolar concentrations[165,223,293]—constitute virtually all the serum ketones. Acetone is a minor component. In severe diabetes, the ratio of β-hydroxybutyrate to acetoacetate may increase

to 6:1 owing to the presence of a large concentration of NADH, which favors β-hydroxybutyrate production.

None of the commonly used methods for the detection and determination of ketone bodies in serum or urine reacts with all three ketone bodies. Gerhardt's ferric chloride test reacts with acetoacetate only. Tests using nitroprusside are at least 10 times more sensitive to acetoacetate than to acetone, and give no reaction at all with β-hydroxybutyrate.

The fact that *most of the tests for ketosis essentially detect or measure acetoacetate only* may produce a paradoxical situation. When a patient initially presents in ketoacidosis, the test results for ketones may be only weakly positive. With therapy, *β-hydroxybutyrate is converted to acetoacetate and the ketosis appears to worsen.*

Traditional tests for β-hydroxybutyrate are indirect; they require brief boiling of the urine to remove acetone and acetoacetate by evaporation (acetoacetate first breaks down spontaneously to acetone), followed by gentle oxidation of β-hydroxybutyrate to acetoacetate and acetone with peroxide, ferric ions, or dichromate. The acetoacetate thus formed may be detected with Gerhardt's test or one of the procedures using nitroprusside.

Specific determination of β-hydroxybutyrate in urine is not considered to be a routine procedure. A paper strip for semiquantitative measurement of β-hydroxybutyrate in serum and urine has been described[115] but has not gained general acceptance. More recently, quantitative enzymatic assays for β-hydroxybutyrate that can be performed directly on blood or serum became commercially available. Originally available commercially as a bench-top analyzer (KetoSite; GDS Diagnostics, Elkhart, Ind.), hand-held devices are also available now (Precision Xtra; MediSense, Boston, and BioScanner Ketone; Polymer Technology Systems, Indianapolis).[50]

Clinical Significance

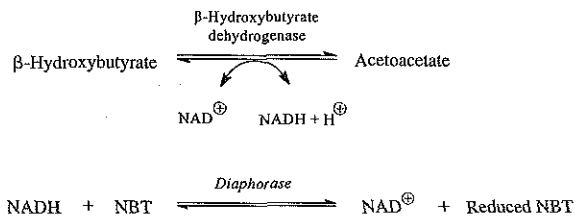
Excessive formation of ketone bodies results in increased blood concentrations (*ketonemia*) and increased excretion in the urine (*ketonuria*). This process is observed in conditions associated with decreased availability of carbohydrates (such as starvation or frequent vomiting) or decreased use of carbohydrates (such as diabetes mellitus, glycogen storage disease [von Gierke's disease], and alkalosis). The popular high-fat, low-carbohydrate diets are ketogenic and increase ketone bodies in the circulation. Diabetes mellitus and alcohol consumption are the most common causes of ketoacidosis in adults. (Hyperglycemia is not usually present in the latter condition.) Ingestion of isopropyl alcohol and salicylate poisoning can also produce ketoacidosis. Urine ketone test results are positive in ~30% of first morning void specimens from pregnant women. Semiquantitative determination of ketone bodies in blood is more accurate than determination of these compounds in urine in the treatment of diabetic ketoacidosis. Although not always excreted in proportion to blood ketone concentrations, because of convenience, urine ketones are widely used for monitoring control in patients with type 1 diabetes. The ADA states that *urine ketone testing is an important part of monitoring by patients with diabetes*, particularly those with type 1 diabetes, pregnancy with preexisting diabetes, and GDM.[108] Patients with type 1 diabetes should test for ketones during acute illness or stress, with consistent increase in blood glucose (greater than 300 mg/dL), during pregnancy, or when symptoms of ketoacidosis are present.[108] Measurement of ketones in urine and blood is widely used in patients with diabetes for both diagnosis and monitoring of diabetic ketoacidosis.[241]

Determination of Ketone Bodies in Body Fluids

Although quantitative determination of individual ketone bodies is possible, these methods are not used as routine tests. The semiquantitative Acetest and Ketostix (Ames Co.) are frequently used but are insensitive to β-hydroxybutyrate.[274] It is important to bear in mind, therefore, that a *negative nitroprusside test result does not rule out ketoacidosis.* (Note: Details of the following tests are found on the Evolve site that accompanies this book.)

Detection of Ketone Bodies by Acetest

The Acetest tablets contain a mixture of glycine, sodium nitroprusside, disodium phosphate, and lactose. Acetoacetate or acetone (to a lesser extent) in the presence of glycine forms a lavender-purple complex with nitroprusside. β-hydroxybutyrate does not react with nitroprusside. The disodium phosphate provides an optimum pH for the reaction, and lactose enhances the color.[138]



Detection of Ketone Bodies by Ketostix

Ketostix is a modification of the nitroprusside test in which a reagent strip is used instead of a tablet. The Ketostix test gives a positive reaction within 15 seconds with a specimen containing at least 50 mg of acetoacetate per L. The accompanying color chart gives readings for ketone concentrations of 50, 150, 400, 800, and 1600 mg/L. Acetone also reacts, but the test is less sensitive to it.

Determination of β-Hydroxybutyrate

A 1995 short report on patients with diabetic ketoacidosis indicated that β-hydroxybutyrate correlated better than acetoacetate with changes in acid-base status.[282]

In this test, β-hydroxybutyrate in the presence of NAD^+ is converted by β-hydroxybutyrate dehydrogenase to acetoacetate, producing NADH. Diaphorase catalyzes the reduction of nitroblue tetrazolium (NBT) by NADH to produce a purple compound and its absorbance is read in a special meter that provides a digital readout.

Determination of Ketone Bodies in Urine

Acetest and Ketostix are also suitable for detecting ketone bodies in urine. The sensitivity and specificity of the tests are the same as outlined for serum.

Reference Interval

Serum β-hydroxybutyrate values range from 0.02 to 0.27 mmol/L (0.21 to 2.81 mg/dL) in healthy people after an overnight fast. Ketone bodies in the blood can reach 2 mmol/L with prolonged exercise.[165] Patients with diabetic ketoacidosis usually have β-hydroxybutyrate concentrations greater than 2 mmol/L (20 mg/dL).

LACTATE AND PYRUVATE

Lactic acid, an intermediate in carbohydrate metabolism (see Figure 25-9), is derived predominantly from white skeletal muscle, brain, skin, renal medulla, and erythrocytes. The blood lactate concentration depends on the rate of production in these tissues and the rate of metabolism in the liver and kidneys. Approximately 65% of total basal lactate production is used by the liver, particularly in gluconeogenesis. The *Cori cycle* is the conversion of glucose to lactate in the periphery and reconversion of lactate to glucose in the liver. Extrahepatic removal of lactate is by oxidation in red skeletal muscle and the renal cortex. A moderate increase in lactate production results in increased hepatic lactate clearance, but uptake by the liver is saturable when concentrations exceed 2 mmol/L. For example, during strenuous exercise, lactate concentrations may increase significantly, from an average concentration of about 0.9 to more than 20 mmol/L within 10 seconds. There is no uniformly accepted concentration for the diagnosis of lactic acidosis, but lactate concentrations exceeding 5 mmol/L and pH less than 7.25 indicate significant lactic acidosis.

Under certain conditions, the ratio of lactate to pyruvate is an indicator of redox status. By rearranging the equation for the equilibrium constant for the reaction catalyzed by lactate dehydrogenase (EC 1.1.1.27), it can be seen that the ratio of lactate to pyruvate is proportional to the ratio of NADH to NAD^+.

Clinical Significance

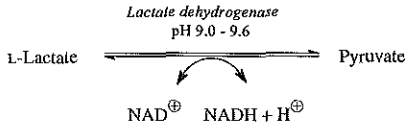
Pyruvate is metabolized by four enzyme systems, namely alanine aminotransferase, pyruvate carboxylase (the major regulatory enzyme in gluconeogenesis), lactate dehydrogenase, and pyruvate dehydrogenase (see Figure 25-9). The last is a complex of enzymes that decarboxylate pyruvate in the presence of oxygen to acetyl coenzyme A (CoA), allowing entry into the citric acid cycle. Measurement of pyruvate is useful in the evaluation of patients with inborn errors of metabolism who have increased serum lactate concentrations. A lactate : pyruvate ratio less than 25 suggests a defect in gluconeogenesis, whereas an increased ratio (greater than or equal to 35) indicates reduced intracellular conditions found in hypoxia. Inborn errors associated with an increased lactate:pyruvate ratio include pyruvate carboxylase deficiency and defects in oxidative phosphorylation.[237] A high lactate : pyruvate ratio appears to be a sensitive test for detecting mitochondrial muscle toxicity of zidovudine therapy.[55] Pyruvate is also measured in clinical studies evaluating reperfusion after myocardial ischemia. Patients with Alzheimer's disease were reported to have higher CSF pyruvate concentrations than control subjects, and the concentrations correlate with the severity of the dementia.[216]

Lactic acidosis occurs in two clinical settings: (1) type A (hypoxic), associated with *decreased tissue oxygenation,* such as shock, hypovolemia, and left ventricular failure; and (2) type B (metabolic), associated with *disease* (e.g., diabetes mellitus, neoplasia, liver disease), *drugs and/or toxins* (e.g., ethanol, methanol, and salicylates), or *inborn errors of metabolism* (e.g., methylmalonic aciduria, propionic acidemia, and fatty acid oxidation defects). Lactic acidosis is not uncommon and occurs in approximately 1% of hospital admissions. It has a mortality rate greater than 60%, which approaches 100% if hypotension is also present. Type A is much more common.

The mechanism of type B lactic acidosis is not known but is speculated to be a primary defect in mitochondrial function with impaired oxygen use. This leads to reduced stores of ATP and NAD^+, with accumulation of NADH and H^+. In the presence of decreased liver perfusion or liver disease, lactate removal from the blood is reduced, thereby aggravating the lactic acidosis.

An uncommon but often undiagnosed cause of lactic acidosis is D-lactic acidosis.[284] It was thought that D-lactate was not produced in human metabolism, but normal individuals have a large capacity to metabolize D-lactate.[284] Moreover, absorption and accumulation of D-lactate from abnormal intestinal bacteria may cause systemic acidosis. This occurs after jejunoileal bypass surgery and manifests as altered mental status (from mild drowsiness to coma) with increased blood concentrations of D-lactate. Virtually all the commonly used laboratory assays for lactate use L-lactate dehydrogenase, which does not detect D-lactate. D-Lactate can be measured by gas-liquid chromatography or, more easily, using a specific D-lactate dehydrogenase (Sigma) from *Lactobacillus leichmanni.*[175] The enzyme assay can be readily automated.

Lactate in CSF normally parallels blood levels, but not in children.[134] With biochemical alterations in the CNS, however, CSF lactate values change independently of blood values. Increased CSF concentrations are noted in cerebrovascular accidents, intracranial hemorrhage, bacterial meningitis, epilepsy, inborn errors of the electron transport chain, and other CNS disorders. In aseptic (viral) meningitis, lactate concentrations in CSF are not usually increased; hence, CSF lactate has been used to help discriminate between viral and bacterial meningitis,[22] but the clinical utility has been questioned. In a few children with inherited metabolic diseases, CSF lactate concentrations may be increased despite a plasma lactate in the reference interval.[134]



Methods for Measuring Lactate and Pyruvate in Body Fluids

(Note: Details of the following tests are found on the Evolve site that accompanies this book.)

Determination of Lactate in Whole Blood[17,172,174,181]

Principle

Lactate is oxidized to pyruvate by lactate dehydrogenase in the presence of NAD^+. The NADH formed in this reaction is measured by a spectrophotometer at 340 nm and serves as a measure of the lactate concentration.

The equilibrium of the reaction normally lies far to the left. However, by using a pH of 9.0 to 9.6, an excess of NAD^+, and trapping the reaction product pyruvate with hydrazine, the equilibrium can be shifted to the right. Pyruvate can also be removed by reacting it with L-glutamate in the presence of alanine aminotransferase. Use of tris (hydroxymethyl)-aminomethane (TRIS) buffer results in more rapid completion of a side reaction between NAD^+ and hydrazine and prevents the "creeping" of blank values observed when glycine buffer is used.[172]

Because of its high specificity and simplicity, the enzymatic method is the method of choice for measuring lactate, although other methods may also be used (e.g., gas chromatography[246] and photometry).

The Vitros analyzer (Ortho-Clinical Diagnostics, Raritan, N.J.) uses an assay in which lactic acid is oxidized to pyruvate by lactate oxidase. The H_2O_2 generated oxidizes a chromogen system, and the absorbance of the resulting dye complex, measured by a spectrophotometer at 540 nm, is directly proportional to the lactate concentration in the specimen. Each mole of lactate oxidized produces 0.5 mol of dye complex.

$$\text{L-Lactate} + O_2 \xrightarrow{\text{Lactate Oxidase}} \text{Pyruvate} + H_2O_2$$

$$2H_2O_2 + \text{4-aminoantipyrine} + \text{1,7-dihydronaphthalene} \xrightarrow{\text{Peroxidase}} \text{red dye}$$

Reference Intervals

The reference intervals for lactate are:

	Lactate	
Specimen	**mmol/L**	**mg/dL**
Venous Blood		
At rest	0.5-1.3	5-12
In hospital	0.9-1.7	8-15
Arterial Blood		
At rest	0.36-0.75	3-7
In hospital	0.36-1.25	3-11

Patients in the hospital exhibit a wider range. Lactic acidosis occurs with blood lactate concentrations exceeding 5 mmol/L (45 mg/dL). Severe exercise dramatically increases lactate concentrations, and even movement of leg muscles by patients at bed rest may result in significant increases. Plasma values are about 7% higher than those in whole blood, although differences depend on the procedure used. CSF values are usually similar to blood concentrations, but may change independently in CNS disorders. Age-related reference intervals for CSF lactate (and lactate:pyruvate ratios) have been established in children.[33] The upper limit of the reference interval (90th percentile) for CSF lactate in children in hospital from birth to 15½ years varied continuously from 1.78 to 1.88 mmol/L (16 to 17 mg/dL).[33] Normal 24-hour urine output of lactate is 5.5 to 22 mmol/day.

Determination of Pyruvate in Whole Blood

Principle

The reaction involved in the determination of pyruvate is essentially the reverse of the reaction used in the lactate procedure.

At about pH 7.5, the equilibrium constant strongly favors the reaction to the right. The method is very specific, and 2-oxoglutarate, oxaloacetate, acetoacetate, and β-hydroxybutyrate do not interfere as with colorimetric methods.

Reference Intervals

Fasting venous blood, drawn with a patient at rest, has a pyruvate concentration of 0.03 to 0.10 mmol/L (0.3 to 0.9 mg/dL). Arterial blood contains 0.02 to 0.08 mmol/L (0.2 to 0.7 mg/dL). Values for CSF are 0.06 to 0.19 mmol/L (0.5 to 1.7 mg/dL).[226] Age-related reference intervals in CSF have been established in children.[33] Urine output of pyruvate is normally 1 mmol/day or less. There are few clinical indications for measurement of blood pyruvate concentrations.

GLYCATED PROTEINS

Measurement of glycated proteins, primarily GHb, is effective in monitoring long-term glucose control in people with diabetes mellitus. It provides a retrospective index of the integrated plasma glucose values over an extended period of time and is not subject to the wide fluctuations observed when assaying blood glucose concentrations. GHb concentrations therefore are a valuable and widely used adjunct to blood glucose determinations for monitoring of long-term glycemic control. In addition, GHb is a measure of the risk for the development of complications of diabetes.

GLYCATED HEMOGLOBIN*

Glycation is the nonenzymatic addition of a sugar residue to amino groups of proteins. Human adult hemoglobin (Hb) usually consists of Hb A (97% of the total), Hb A_2 (2.5%), and Hb F (0.5%). Hb A is made up of four polypeptide chains, two α- and two β-chains. Chromatographic analysis of Hb A identifies several minor hemoglobins, namely Hb A_{1a}, Hb A_{1b}, and Hb A_{1c},which are collectively referred to as Hb A_1, *fast hemoglobins* (because they migrate more rapidly than Hb A in an electrical field), *glycohemoglobins,* or *glycated hemoglobins* (Table 25-6). The Joint Commission on Biochemical Nomenclature of the International Union of Pure and Applied Chemistry recommends the term *neoglycoprotein* for such derivatives and the term *glycation* to describe this process. Therefore although *glycosylated* and *glucosylated* have been widely used in the literature, the term *glycated* is preferred. Hb A_{1c} is formed by the condensation of glucose with the *N*-terminal valine residue of each β-chain of Hb A to form an unstable Schiff base (aldimine, pre-Hb A_{1c}; Figure 25-15). The Schiff base may either dissociate or undergo an Amadori rearrangement to form a stable ketoamine, Hb A_{1c}. Hb A_{1a1} and Hb A_{1a2}, which make up Hb A_{1a}, have fructose-1,6-diphosphate and glucose-6-phosphate, respectively, attached to the amino terminal of the β-chain (Table 25-6). The structure of Hb A_{1b}, identified by mass spectrometry, contains pyruvic acid linked to the amino terminal valine of the β-chain, probably by a ketamine or enamine bond. *Hb A_{1c} is the major fraction,* constituting approximately 80% of Hb A_1.

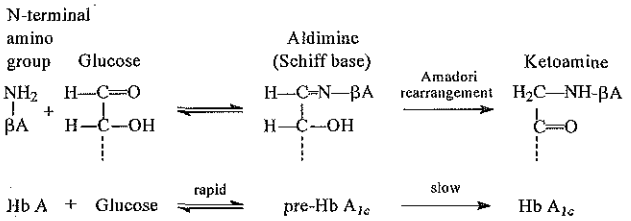


Figure 25-15 Formation of hemoglobin A_{1c}.

Glycation may also occur at sites other than the end of the β-chain, such as lysine residues, or the α-chain. These GHbs, referred to as glycated Hb A_0 or total glycated hemoglobin (Table 25-6), cannot be separated from nonglycated hemoglobin by methods based on charge, but are measured by boronate affinity chromatography.

Formation of GHb is essentially irreversible, and the concentration in the blood depends on both the lifespan of the red blood cell (average 120 days) and the blood glucose concentration. Because the rate of formation of GHb is directly proportional to the concentration of glucose in the blood, *the GHb concentration represents the integrated values for glucose over the preceding 6 to 8 weeks.* This provides an additional criterion for assessing glucose control because GHb values are free of day-to-day glucose fluctuations and are unaffected by recent exercise or food ingestion. It is important to realize that the contribution of the plasma glucose concentration to GHb depends on the time interval, with more recent values providing a larger contribution than earlier values. The

*The terms glycated hemoglobin, glycohemoglobin, "glycosylated" (which should not be used as it refers to proteins in which carbohydrates have been attached enzymatically) hemoglobin, Hb A_1, and Hb A_{1c}, have all been used to refer to hemoglobin that has been modified by the nonenzymatic addition of glucose residues. However, these terms are not interchangeable. Glycated hemoglobins comprise Hb A_1 and other hemoglobin-glucose adducts, whereas Hb A_1 is made up of Hb A_{1a}, Hb A_{1b}, and Hb A_{1c}. To eliminate this confusing nomenclature, the term "A1c test" has been suggested. As described in the text, most of the clinical outcome data that are available for the effects of metabolic control on complications (at least for the DCCT and UKPDS) used assay methods that quantified HbA_{1c}. In this chapter, the term glycated hemoglobin includes all forms of glycated hemoglobin.

TABLE 25-6 Nomenclature of Selected Hemoglobins

Name	Component(s)
Hb A	Constitutes ~97% adult hemoglobin
Hb A_0	Synonymous with Hb A
Hb A_{1a1}	Hb A with fructose-1,6-diphosphate attached to the *N*-terminal of the β-chain
Hb A_{1a2}	Hb A with glucose-6-phosphate attached to the *N*-terminal of the β-chain
Hb A_{1a}	Comprises Hb A_{1a1} and Hb A_{1a2}
Hb A_{1b}	Hb A with pyruvic acid attached to the *N*-terminal of the β-chain
Hb A_{1c}	Hb A with glucose attached to the *N*-terminal valine of the β-chain
pre-Hb A_{1c}	Unstable Schiff base (aldimine); a labile intermediary component in the formation of Hb A_{1c}
Hb A_1	Consists of Hb A_{1a}, Hb A_{1b}, and Hb A_{1c}
Total glycated hemoglobin*	Consists of Hb A_{1c} and other hemoglobin-carbohydrate adducts

Hb, Hemoglobin
*Also termed "glycated hemoglobin" or "glycohemoglobin"

plasma glucose in the preceding 1 month determines 50% of the Hb A_{1c}, whereas days 60 to 120 determine only 25%.[267] After a sudden alteration in blood glucose concentrations, the rate of change of Hb A_{1c} is rapid during the initial 2 months, followed by a more gradual change approaching steady state 3 months later. The half-time is 35 days.

The interpretation of GHb depends on the red blood cells having a normal lifespan. Patients with hemolytic disease or other conditions with shortened red blood cell survival exhibit a substantial reduction in GHb.[46] Similarly, individuals with recent significant blood loss have falsely low values owing to a higher fraction of young erythrocytes. GHb concentrations can still be used to monitor these patients, but values must be compared with previous values from the same patient, not published reference intervals. High GHb concentrations have been reported in iron deficiency anemia, probably because of the high proportion of old erythrocytes. The effect of hemoglobin variants (such as Hb F, Hb S, and Hb C) depends on the specific method of analysis (discussed later).[46] Depending on the particular hemoglobinopathy and assay method, results may be spuriously increased or decreased. Another source of error in selected methods is *carbamylated hemoglobin.* This is formed by attachment of urea and is present in large amounts in renal failure, which is common in diabetic patients.

Labile intermediates (pre-Hb A_{1c}, Schiff base) may be included in measurements of Hb A_{1c}, especially in the common electrophoretic and ion-exchange methods,[195] and produce misleadingly high results. The *labile fraction changes rapidly with acute changes in blood glucose concentration and thus is not an indicator of long-term glycemic control.* Pre-Hb A_{1c} amounts to 5% to 8% of total Hb A_1 in healthy individuals and ranges from 8% to 30% in patients with diabetes, depending on the degree of control of blood glucose concentration at or near the time of blood sampling.[133] If the analytical method measures both fractions, the labile pre-Hb A_{1c} should first be removed to prevent falsely increased results. In the absence of glucose, pre-Hb A_{1c} reverts to glucose and Hb A (see Figure 25-15). This provides the basis for some procedures to eliminate the labile fraction by incubating washed red blood cells in saline. In some boronate methods, the assay conditions favor rapid dissociation of the Schiff base.

Clinical Utility

GHb has been firmly established as an index of long-term blood glucose concentrations and as a measure of the risk for the development of complications in patients with diabetes mellitus.[107] GHb was a cornerstone of the DCCT.[72] (To prevent assay variability [see section on assay standardization later in this chapter], all GHb assays in the DCCT were done in a central laboratory that measured Hb A_{1c} by HPLC.) The DCCT documented that there is a direct relationship between blood glucose concentrations (assessed by Hb A_{1c}) and the risk of complications.[72] The absolute risks of retinopathy and nephropathy were directly proportional to the mean Hb A_{1c}. The risk of retinopathy increased continuously with increasing Hb A_{1c}, and a single measure of Hb A_{1c} predicted the progression of retinopathy 4 years later. In fact, subsequent analysis revealed that the mean Hb A_{1c} was the dominant predictor of retinopathy progression, and a 10% lower Hb A_{1c} concentration was associated with a 45% lower risk.[73] The risk of microvascular complications varies continuously with Hb A_{1c} and there is not an Hb A_{1c} concentration below which the risk is eliminated.

Analogous correlations between Hb A_{1c} and complications were observed in patients with type 2 diabetes in the UKPDS trial.[280] To ensure that Hb A_{1c} results in the UKPDS were comparable with the DCCT, the same ion-exchange HPLC method was used. The mean Hb A_{1c} values for the intensively treated and conventional groups were 7.0% and 7.9%, respectively.[280] Despite the apparently small difference in Hb A_{1c}, microvascular complications were reduced by ~25%. Each 1% reduction in Hb A_{1c} (e.g., from 8% to 7%) was associated with risk reductions of 37% for microvascular disease, 21% for deaths related to diabetes, and 14% for myocardial infarction.[280] Importantly, in patients without diabetes, Hb A_{1c} is directly related to cardiovascular disease. In the European Prospective Investigation into Cancer and Nutrition [EPIC-Norfolk], an increase of 1% in Hb A_{1c} was associated with a 28% increase in the risk of death.[150] Based on the DCCT and UKPDS, the ADA recommends that a primary treatment goal in adults with diabetes should be "near-normal" glycemia with Hb A_{1c} less than 7%.[15] The American College of Endocrinology and the International Diabetes Federation recommend a Hb A_{1c} target of 6.5%. The more frequent use of this test in the management of patients is reflected in the increased number of laboratories participating in College of American Pathologists (CAP) GHb surveys. In 1985, 1990, and 2003 there were approximately 300, 707, and 2008 laboratories, respectively, enrolled in the GHb surveys.

Methods for the Determination of Glycated Hemoglobins

There are more than 30 different methods for the determination of GHbs. These methods separate hemoglobin from GHb using techniques based on *charge differences* (ion-exchange chromatography, HPLC, electrophoresis, and isoelectric focusing), *structural differences* (affinity chromatography and immunoassay), or *chemical analysis* (photometry and spectrophotometry).[109] Regardless of the method, the result is expressed as a percentage of total hemoglobin. Analysis by chemical techniques is rarely used and is not addressed further here. (Interested readers are referred to earlier editions of this book.) The selection of method by a laboratory is influenced by several factors, including sample volume, patient population, and cost. It is advisable to consult clinicians in this process. The ADA recommends that laboratories should use only GHb assays that are

TABLE 25-7 Methods of Glycated Hemoglobin Analysis[a]

		Year: 1995 (n = 1947)[b]				2003 (n = 2008)

CV, Coefficient of variation; *Hb,* hemoglobin; *GHb,* glycated hemoglobin.

[a]Results are based on 1995 CAP Survey, Set EC-B, Specimen GH-03 and 2003 CAP Survey, Set GH2-A, Specimen GH2-02 (Copyright, 1995 and 2003 College of American Pathologists; data used with permission). See text for discussion of methods.

[b]n is the number of laboratories that participated in the survey.

[c]Indicates how many laboratories use the indicated method.

[d]Where more than one value is listed, the data vary among commercial assays. The range is presented.

[e]The NGSP value in 2003 was 5.2%.

[f]Number of participants was too low to permit statistical analysis.

certified by the National Glycohemoglobin Standardization Program (now known as the NGSP) as traceable to the DCCT reference.[15,241]

The GHb assays most widely used in the United States are depicted in Table 25-7. These data are based on results from 1947 laboratories participating in a 1995 quality control survey and 2008 laboratories participating in a 2003 quality control survey conducted by the CAP. The results demonstrate that in 2003 virtually all laboratories used immunoassay or ion-exchange chromatography. Hb A_{1c} was measured by more than 99% of laboratories (Table 25-7). Total GHb and Hb A_1 measurements had virtually disappeared. These results reflect significant changes from the methods used in 1995 when affinity chromatography was the most common analytical method (Table 25-7). Also, only 60% of laboratories reported Hb A_{1c} in 1995. In addition, the variation among mean values—both between and within methods—and imprecision were substantially lower in 2003. It should be borne in mind that these data refer only to these CAP surveys and are weighted to laboratories that participate. All of the methods described are commercially available from several different manufacturers. Moreover, differences in means among methods may reflect calibration and other differences in addition to inherent differences between methods.

Ion-Exchange Minicolumns

Ion-exchange chromatography separates hemoglobin variants on the basis of charge. The cation exchange resin (negatively charged), packed in a disposable minicolumn, has an affinity for hemoglobin, which is positively charged. The patient's sample is hemolyzed and an aliquot of the hemolysate is applied to the column. A buffer is applied and the eluent collected. The ionic strength and pH of the eluent buffer are selected so that GHbs are less positively charged than Hb A, do not bind as well to the negatively charged resin, and are therefore eluted first. The GHbs—A_{1a} + A_{1b} + A_{1c}, expressed collectively as Hb A_1—are measured in a spectrophotometer. A second buffer of different ionic strength can be added to the column to elute the more positively charged main hemoglobin fraction. This is read in the spectrophotometer and GHb is expressed as a percentage of total hemoglobin. Alternatively, only the Hb A_1 is eluted and a separate dilution of the original hemolysate is made, against which the Hb A_1 is compared. Numerous commercial modifications have been developed. Simple agitation of resins with hemolysates (batch technique) to adsorb Hb A has also been described. In this approach, the supernatant solution containing the Hb A_1 fraction is removed by filtration or centrifugation. Methods that separate Hb A_{1a+b} from Hb A_{1c} by using two different buffers have also been described.[180] Most of the current commercial ion-exchange methods use HPLC.

In all ion-exchange column methods, it is important to *control the temperature of the reagents and columns* to obtain accurate and reproducible results. This is best done by thermostatting the columns. Alternatively, a temperature correction factor can be applied if the room temperature differs

from the specified optimum. In addition, rigid control of pH and ionic strength must be maintained. Sample storage conditions are also important.

The labile pre-Hb A_1 fractions elute with the stable ketoamine and produce spuriously high values unless destroyed by pretreatment of the red blood cells. Spuriously increased values are also obtained when the charge on hemoglobin is altered by the attachment of noncarbohydrate moieties, which may co-chromatograph with GHbs, as in uremia (carbamylated hemoglobin), alcoholism, lead poisoning, or chronic treatment with large doses of aspirin (acetylated hemoglobin). Hemoglobin variants or chemically modified hemoglobin that elute separately from Hb A and Hb A_{1c} have little effect on Hb A_{1c} measurements. If the modified hemoglobin (or its glycated derivative) cannot be separated from Hb A or Hb A_{1c}, spuriously increased or reduced results will be obtained.[46] A variant that elutes with Hb A_{1c} will yield a gross overestimation of Hb A_{1c}, and a variant that co-elutes with Hb A will underestimate Hb A_{1c}. Note that a single variant may falsely increase or decrease Hb A_{1c}, depending on the method used.[46]

High-Performance Liquid Chromatography

Hb A_{1c} and other hemoglobin fractions can be separated by HPLC, which employs cation-exchange chromatography.[71] Several fully automated systems are commercially available. Assays require only 5 μL of whole blood, and fingerstick samples can be collected in a capillary tube for analysis. Anticoagulated blood is diluted with a hemolysis reagent containing borate. Samples are incubated at 37 °C for 30 minutes to remove Schiff base and inserted in the autosampler. (Some instruments have a shorter preincubation step, and others [e.g., Tosoh A_{1c}2.2], separate labile A_{1c} chromatographically, eliminating the step to remove the Schiff base.)[103] A step gradient using three phosphate buffers of increasing ionic strength is passed through the column. Detection is performed at both 415 and 690 nm, and results are quantified by integrating the area under the peaks. Analysis time is as short as 3 to 5 minutes. All HPLC methods had CVs less than 3.5% in a 2003 CAP survey. Hb A_{1c} by HPLC was used for analysis of all patient samples in the DCCT[71] and UKPDS.

Electrophoresis

Agar gel electrophoresis on whole-blood hemolysates at pH 6.3 provides good resolution of Hb A and Hb A_1.[185] The gel contains negatively charged moieties that interact with the hemoglobin. After 25 to 35 minutes, the GHb separates on the cathodic side of Hb A. Quantification is performed by scanning densitometry at 415 nm. Results generally agree well with those obtained by HPLC or column chromatography, but are less precise.[185] Minor variations in pH, ionic strength, or temperature have little effect on results. Hb F migrates to the same region as Hb A_1 and causes a falsely increased Hb A_1 value, but Hb S and Hb C do not. The labile form should be removed before assaying.

Isoelectric Focusing

The hemoglobin variants separate on isoelectric focusing on the basis of their migration in gel containing a pH gradient.[262] Ampholines in the pH range of 6 to 8 establish the gradient in 1-mm-thick acrylamide gel slabs. As many as 35 samples per gel slab can be individually applied to filter paper tabs. On completion of isoelectric focusing, the gels are fixed and then scanned on a high-resolution integrating microdensitometer. Hb A_{1c} is adequately resolved from Hb A_{1a}, A_{1b}, S, and F. Results showed close agreement with other methods. The equipment is expensive and is not widely used in the United States, but is more popular in Europe.

Immunoassay

Assays for Hb A_{1c} have been developed using antibodies raised against the Amadori product of glucose (ketoamine linkage) plus the first few (four to eight) amino acids at the *N*-terminal end of the β-chain of hemoglobin.[85,139] A widely used assay measures Hb A_{1c} in whole blood by inhibition of latex agglutination. The agglutinator, a synthetic polymer containing multiple copies of the immunoreactive portion of Hb A_{1c}, binds the anti-Hb A_{1c} monoclonal antibody that is attached to latex beads. This agglutination produces light scattering, measured as an increase in absorbance. Hb A_{1c} in the patient's sample competes for the antibody on the latex, inhibiting agglutination, thereby decreasing light scattering. Enzyme immunoassays using monoclonal antibodies are commercially available and most exhibit low imprecision (see Table 25-7). These assays have been shown to correlate well with HPLC. The antibodies do not recognize labile intermediates or other GHbs (such as Hb A_{1a} or Hb A_{1b}) because both the ketoamine with glucose and the specific amino acid sequences are required for binding. Similarly, other hemoglobin variants, such as Hb F, Hb A_2, Hb S, and carbamylated hemoglobin are not detected.[46] The procedure has been adapted for capillary blood samples using a bench-top analyzer with reagent cartridges designed for use in physicians' office laboratories.

Affinity Chromatography

Affinity gel columns are used to separate GHb, which binds to the column, from the nonglycated fraction. *m*-Aminophenylboronic acid is immobilized by cross-linking to beaded agarose or another matrix (e.g., glass fiber). The boronic acid reacts with the *cis*-diol groups of glucose bound to hemoglobin to form a reversible five-member ring complex, thus selectively holding the GHb on the column (Figure 25-16). The nonglycated hemoglobin does not bind. Sorbitol is then added to elute the GHb. Absorbance of the bound and nonbound fractions, measured at 415 nm, is used to calculate the percentage of GHb.

A commercial assay is performed on an automated analyzer that uses a soluble reagent consisting of dihydroxyboronate coupled to high molecular weight polyacrylic acid.[294] GHb binds to the boronate. The polyanionic-glycated hemoglobin affinity complex attaches by electro-

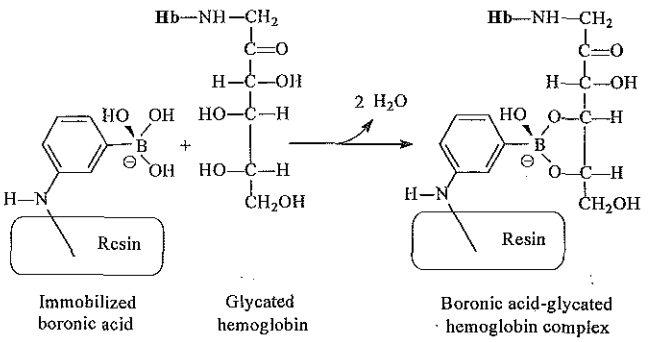

Figure 25-16 Reaction of GHb with immobilized boronic acid.

static interactions to the cationic surface of the solid phase matrix (ion capture). Nonglycated hemoglobin does not bind and is removed in a wash step. GHb is quantified by measuring the quenching by hemoglobin of the fluorescence of an added fluorophore, 4-methyl-umbelliferone. Total hemoglobin is determined by fluorescence quenching of a second sample containing sorbitol. The sorbitol competes for boronate binding sites, and both nonglycated and GHb contribute to inhibition of the quenching. The fluorescence measurements are converted to glycated and total hemoglobin concentrations from separate stored calibration curves.

The major advantages of affinity chromatography are as follows: There is no interference from nonglycated hemoglobins and negligible interference from the labile intermediate form of Hb A_{1c}. It is unaffected by variations in temperature and has reasonably good precision. Hemoglobin variants such as Hb F, Hb S, or Hb C produce little effect. Affinity methods measure total GHb. This includes components other than Hb A_{1c} because the assay detects ketoamine structures on lysine and valine residues on both α- and β-chains of hemoglobin.

Although the method detects all GHbs, several commercially available systems are calibrated to also report an Hb A_{1c} standardized value. The latter are derived from an equation obtained from correlation between total GHb and Hb A_{1c} analysis by HPLC.[294] A linear relationship has been demonstrated, and standardized Hb A_{1c} values are thus comparable with the values obtained by methods specific for Hb A_{1c}. Columns and reagents are readily available from a number of manufacturers, several of whom have automated the procedure.

Removal of Labile Glycated Hemoglobin from Red Blood Cells

The concentration of the labile form of Hb A_{1c} (Schiff base) fluctuates rapidly in response to acute changes in plasma glucose concentrations and should be removed before analysis by charge-based assays. This may be accomplished by incubating red blood cells in saline[110] or in buffer solutions at pH 5 to 6,[27] or by dialysis or ultrafiltration of hemolysates. Most kits for column assays contain reagents to remove this labile component.

Assay Standardization

Clinical laboratories measure GHb with diverse assays that use multiple methods and quantify different components. The DCCT results accentuated the need for accurate GHb measurement and provided a strong impetus for standardization of GHb assays. At the end of the DCCT, it was noted that the absence of both a reference method and a single GHb standard had generated confusion.[245] Interlaboratory comparisons were not possible, and even a single quality-control sample analyzed by a single method exhibited CVs as high as 16.5%. Similar large variability among laboratories was observed in Europe.[104] Committees were established under the auspices of the American Association for Clinical Chemistry and the International Federation of Clinical Chemistry and Laboratory Medicine (IFCC) to standardize GHb assays.

The NGSP (http://web.missouri.edu/~diabetes/ngsp.html) was implemented in 1996 to calibrate GHb results to DCCT-equivalent values. Employing a network of reference laboratories, the NGSP interacts with manufacturers of GHb methods to help them calibrate their methods and trace the values to the DCCT.[171] Manufacturers apply for certification by performing precision testing following NCCLS EP5-A guidelines and report results in DCCT-equivalent hemoglobin A_{1c} values. This calibration effort has markedly improved harmonization of results and reduced imprecision.[171] Results obtained using NGSP-certified assays can be compared with the results of the DCCT and UKPDS, allowing alignment to clinical outcomes data. The ADA recommends that clinical laboratories use only assays certified by the NGSP and participate in proficiency testing offered by the CAP. The CAP-GH2 survey uses pooled whole blood specimens at three GHb concentrations. Target values are assigned by the NGSP network. Thus individual laboratories can directly compare their GHb results with those of the DCCT.

A different approach was adopted by the IFCC. In 1995 a working group was established to devise a reference system for standardization based on Hb A_{1c}. The IFCC group developed a mixture of purified Hb A_{1c} and Hb A_0 as primary reference material.[159] Two candidate reference methods, namely electrospray ionization mass spectrometry (ESI-MS) and capillary electrophoresis, were proposed.[159] These specifically measure the glycated *N*-terminal valine of the β-chain of hemoglobin. Analysis is performed by digesting the hemoglobin molecule with endoproteinase Glu-C, which cleaves the β-chain between Glu-6 and Glu-7, releasing the *N*-terminal hexapeptide. The glycated and nonglycated hexapeptides are separated and quantified by HPLC-ESI-MS or by HPLC-capillary electrophoresis.[159] Hb A_{1c} is measured as the ratio between glycated and nonglycated *N*-terminal hexapeptides. Comparisons between the IFCC and NGSP reference methods (and other reference systems, including others from Japan and Sweden) are under investigation.

Initial analysis indicates a close and stable relationship. However, the Hb A_{1c} results obtained using IFCC reference methods are 1.5% to 2% lower than those of the NGSP (and lower than other reference systems). The difference is probably due to measurement of glycated components other than Hb A_{1c} by the HPLC used by the NGSP. International harmonization would allow worldwide alignment of GHb results with patient outcomes in DCCT and UKPDS. If the IFCC reference method exhibits long-term stability and has a robust relationship with the NGSP, the IFCC method may eventually become the reference method for the NGSP. Consultations among clinicians and laboratorians have been initiated to reach an international consensus on how to reconcile the different Hb A_{1c} values between the standardization programs, with the ultimate goal of enhancing patient care.

Specimen Collection and Storage

Patients need not be fasting. Venous blood should be collected in tubes containing EDTA, oxalate, or fluoride. Sample stability depends on the assay method.[241] Whole blood may be stored at 4 °C for up to 1 week. Above 4 °C, Hb A_{1a+b} increases in a time- and temperature-dependent manner, but Hb A_{1c} is only slightly affected.[259] Storage of samples at −20 °C is not recommended. For most methods, whole blood samples stored at −70 °C are stable for at least 18 months.[83] Heparinized samples should be assayed within 2 days and may not be suitable for some methods of analysis (e.g., electrophoresis).

Reference Intervals

Values for GHbs are expressed as a percentage of total blood hemoglobin. One of three major GHb species, namely Hb A_1, Hb A_{1c}, or total GHb, is usually measured. In the United States, the vast majority of laboratories now measure Hb A_{1c}. Reference intervals vary, depending on the GHb component measured and whether the labile fraction is included in the assay. A consensus, based on several studies of apparently healthy subjects, suggests the following reference intervals:

	Mean (%)	Interval (%)
Hb A_1 (A_{1a+b+c})	6.5	5.0-8.0
Hb A_{1c} only (DCCT-equivalent)	4.5	4.0-6.0
Total glycated Hb ($A_1 + A_0$)	5.5	4.5-7.0

The effects of age on reference intervals are controversial.[241] Some studies show age-related increases (~0.1% per decade after age 30), and other reports show no increase.[151,292] Results are not affected by acute illness. Intraindividual variability is minimal.[238] In patients with poorly controlled diabetes mellitus, values may extend to twice the upper limit of the reference interval or more but rarely exceed 15%. Values greater than 15% should prompt further studies to determine the possible presence of variant hemoglobin.[46] Note that ADA target values derived from DCCT and UKPDS, not the reference values, are used to evaluate metabolic control in patients.

There is no specific value of Hb A_{1c} below which the risk of diabetic complications is eliminated completely. The ADA states that the goal of treatment should be to maintain Hb A_{1c} less than 7%.[15] (Some organizations recommend an Hb A_{1c} target of less than 6.5%.) These values are applicable only if the assay method is certified as traceable to the DCCT reference. Each laboratory should establish its own nondiabetic reference interval. Assay precision is important because each 1% change in Hb A_{1c} represents an approximate 35 mg/dL change in average blood glucose.

There is no consensus on optimum frequency of testing. The ADA recommends that *GHb should be routinely monitored at least every 6 months in patients meeting treatment goals (and who have stable glycemic control).*[15] These recommendations are for patients with either type 1 or type 2 diabetes. In certain clinical situations, such as diabetic pregnancy, when patients are not meeting treatment goals, or a major change in therapy, more frequent monitoring (e.g., every 3 months) may provide useful information.

FRUCTOSAMINE

Clinical Significance

In selected patients with diabetes mellitus (e.g., GDM or change in therapy), there may be a need for assays that are more sensitive than GHb to shorter-term alterations in average blood glucose levels. Nonenzymatic attachment of glucose to amino groups of proteins other than hemoglobin (e.g., serum proteins, membrane proteins, and lens crystallins) to form ketoamines also occurs. Because serum proteins turn over more rapidly than erythrocytes (the circulating half-life for albumin is about 20 days), *the concentration of glycated serum albumin reflects glucose control over a period of 2 to 3 weeks.* Therefore evidence of both deterioration of control and improvement with therapy is evident earlier than with GHb.

Fructosamine is the generic name for plasma protein ketoamines (for reviews, see Armbruster[16] and Hill et al[121]). The name refers to the structure of the ketoamine rearrangement product formed by the interaction of glucose with the ε-amino group on lysine residues of albumin. Analogous to GHb, measurement of fructosamine may be used as an index of the average concentration of blood glucose over an extended period of time.

Because all glycated serum proteins are fructosamines and albumin is the most abundant serum protein, measurement of fructosamine is thought to be largely a measure of glycated albumin, but this has been questioned by some investigators.[250] Although the fructosamine assay can be automated and is cheaper and faster than GHb, *there is a lack*

of consensus on its clinical utility. For example, evaluation of 65 studies led the authors to conclude that fructosamine determination is not a reliable test and has not been evaluated sufficiently for routine clinical use.[296] In contrast, a review of essentially the same data concluded that fructosamine could provide information useful in the management of diabetes.[16] Early work using the original assay, introduced in 1983,[23,141] indicated that fructosamine concentrations were significantly higher in diabetic individuals than in healthy subjects. Over the succeeding decade, the assay underwent numerous modifications because several artifacts were identified that rendered the data from the first-generation fructosamine assay difficult to interpret. These include an apparent lack of specificity for glycated proteins (up to 60% of the value was due to nonfructosamine reducing substances), lack of standardization among laboratories, difficulty in calibrating the assay, and interference by urates and hyperlipidemia.[31] Substantial modifications produced second-generation assays that contain uricase and higher detergent concentrations and are calibrated with glycated lysine.[251] In addition, an industry standard was adopted. These improvements resulted in average fructosamine values in nondiabetics that are approximately 10% of those obtained with the first-generation assay. Some clinical evidence suggests that fructosamine may be useful in the elderly[52] and in pregnancy.[148] The potential role of the second-generation fructosamine assay in providing rapid, reliable, inexpensive, and technically easy monitoring of glycemic control requires evaluation. The clinical value of fructosamine has not been firmly established, and there is no convincing evidence that relates its concentration to the chronic complications of diabetes.[241]

As fructosamine determination monitors short-term glycemic changes different from GHb, it may have a role in conjunction with GHb rather than instead of it. In addition, *fructosamine may be useful in patients with hemoglobin* variants, such as Hb S or Hb C, that are associated with decreased erythrocyte lifespan where GHb is of little value. Gross changes in protein concentration and half-life may have large effects on the proportion of protein that is glycated. Thus fructosamine results may be invalid in patients with nephrotic syndrome, cirrhosis of the liver, or dysproteinemias, or after rapid changes in acute phase reactants. Initial reports indicated that, in the absence of significant alterations in serum protein concentrations, fructosamine results were independent of protein concentrations.[24] However, this observation has been questioned by other investigators who recommend that fructosamine values be corrected for protein concentrations. This issue remains to be resolved. It is generally accepted that the test should not be performed when serum albumin is less than 30 g/L. Although it was initially postulated that the fructosamine assay would replace the OGTT, *there is no role for the fructosamine assay in the diagnosis of diabetes mellitus.* The second-generation fructosamine assay has been reported to have a sensitivity and specificity of close to 80% in screening patients for GDM[132] but this study requires verification.

Determination of Fructosamine

Methods for measuring glycated proteins include (1) affinity chromatography using immobilized phenylboronic acid (similar to the GHb assay)[300]; (2) HPLC of glycated lysine residues after hydrolysis of the glycated proteins[249]; (3) a photometric procedure in which mild acid hydrolysis releases 5-hydroxymethylfurfural—proteins are precipitated with trichloroacetic acid and the supernatant is reacted with 2-thiobarbituric acid[81]; and (4) other procedures using phenylhydrazine and ε-*N*-(2-furoylmethyl)-L-lysine (furosine). None of these assays is popular because they are not suitable for routine clinical laboratories. The development of monoclonal antibodies to glycated albumin,[64] although theoretically advantageous, has not yet resulted in the widespread availability of commercial glycated albumin assays. It should be noted that prolonged storage at ultra-low temperatures (−96 °C) prevents in vitro glycation of serum proteins.[25]

An alternative method for the measurement of fructosamine is a modification[170,251] of the original method of Johnson and colleagues,[141] details of which are included in the Evolve site that accompanies this book. This method is conducted under alkaline conditions and results in fructosamine undergoing an Amadori rearrangement and the resultant compounds having reducing activity that can be differentiated from other reducing substances. In the presence of carbonate buffer, fructosamine rearranges to the eneaminol form, which reduces NBT to a formazan (Figure 25-17). The absorbance at 530 nm is measured at two time points and the absorbance change is proportional to the fructosamine concentration. A 10-minute preincubation is necessary to allow fast-reacting interfering reducing substances to react. It is unnecessary to remove endogenous glucose from patients' samples because a pH greater than 11 is required for glucose to reduce NBT. The assay is easily automated and has excellent between-batch analytical precision. Hemoglobin (greater than 100 mg/dL) and bilirubin (greater than 4 mg/dL) interfere; therefore moderate to grossly hemolyzed and icteric samples should not be used. Ascorbic acid concentrations greater than 5 mg/dL may cause negative interference. Kits are commercially available

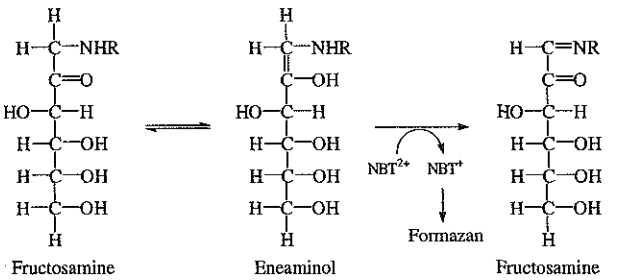

Figure 25-17 Reaction of fructosamine with NBT.

(Roche Diagnostics, Indianapolis). An assay that measures fructosamine by oxidizing the ketoamine bond using ketoamine oxidase, with the release of H_2O_2 that is quantified by a photometric reaction, is available (Randox, Oceanside, Calif.). An FDA-approved device using a hand-held meter for home use by adults excluding pregnant women and children (InCharge, LXN Corp., San Diego) has been discontinued.

Reference Intervals

Values in a nondiabetic population range from 205 to 285 μmol/L. The reference interval corrected for albumin is 191 to 265 μmol/L.

Advanced Glycation End Products

The molecular mechanism by which hyperglycemia produces toxic effects is unknown, but glycation of tissue proteins may be important. Nonenzymatic attachment of glucose to long-lived proteins, such as collagen or DNA, produces stable Amadori early-glycated products. These undergo a series of additional rearrangements, dehydration, and fragmentation reactions, resulting in stable *advanced glycation end products* (AGE). The amounts of these products do not return to normal when hyperglycemia is corrected, and they accumulate continuously over the lifespan of the protein. Hyperglycemia accelerates the formation of protein-bound AGE, and patients with diabetes mellitus thus have more AGE than healthy subjects. Through effects on the functional properties of protein and extracellular matrix, AGE may contribute to the microvascular and macrovascular complications of diabetes mellitus.[44,281] Moreover, an inhibitor of AGE formation, aminoguanidine, has been shown to prevent several of the complications of diabetes in experimental animal models and is undergoing clinical trials in patients.

Several assays for AGE have been developed. An early method, AGE-dependent relative *fluorescence,* suffered from spurious contributions to total fluorescence by non-AGE protein adducts, such as glucose- or lipid-derived oxidation products, that have similar fluorescence spectra. A *radioreceptor assay,* based on the presence of AGE receptors on the surface of a macrophage-like tumor cell line, that was capable of quantifying AGE on both circulating (albumin) and tissue proteins was developed.[227] *Antibodies* were also raised against AGE–keyhole limpet hemocyanin[198] and AGE-bovine serum albumin.[127] These antibodies react with several AGE-proteins. A competitive ELISA using polyclonal anti-AGE antibody was developed to measure hemoglobin-AGE.[178] Using this assay, a linear correlation was demonstrated between Hb A_{1c} and hemoglobin-AGE. In healthy people, hemoglobin-AGE accounts for 0.4% of circulating hemoglobin, with significantly higher values in patients with diabetes mellitus. After an acute change in glycemia, hemoglobin-AGE levels change, but the rate of alteration is 23% slower than that of Hb A_{1c}.[297] Thus hemoglobin-AGE provides a measure of diabetic control longer than that indicated by GHb, reflecting blood glucose concentrations over a greater proportion of the life of red blood cells. It remains to be established whether knowledge of hemoglobin-AGE values offers clinical benefit.

URINARY ALBUMIN EXCRETION

Clinical Significance

Patients with diabetes mellitus are at high risk of suffering renal damage. End-stage renal disease requiring dialysis or transplantation develops in approximately one third of patients with type 1 diabetes,[229] and diabetes is the most common cause of end-stage renal disease in the United States and Europe.[193] Although nephropathy is less common in patients with type 2 diabetes, approximately 60% of all cases of diabetic nephropathy occur in these patients because of the higher incidence of this form of diabetes. Early detection of diabetic nephropathy relies on tests of urinary excretion of albumin. Persistent proteinuria detectable by routine screening tests (equivalent to a urinary albumin excretion [UAE] rate greater than or equal to 200 μg/min) indicates overt diabetic nephropathy. This is usually associated with long-standing disease and is unusual less than 5 years after the onset of type 1 diabetes. Once diabetic nephropathy occurs, renal function deteriorates rapidly and renal insufficiency evolves. Treatment at this stage can retard the rate of progression but not stop or reverse the renal damage. Preceding this stage is a period of increased UAE not detected by routine methods. This range of 20 to 200 μg/min (or 30 to 300 mg/24 hr) of increased UAE defines *microalbuminuria.* Note that it is not defined in terms of urinary albumin concentration, although the albumin:creatinine ratio can be used as a substitute for albumin measurements in a time collection of urine as described below. The term *microalbuminuria,* although generally accepted, is misleading. It implies a small version of the albumin molecule rather than an excretion rate of albumin greater than normal but less than that detectable by routine methods. A more accurate term would be *paucialbuminuria,* but the term microalbuminuria is well entrenched and is unlikely to be superseded.

The presence of increased UAE denotes an increase in the transcapillary escape rate of albumin and is therefore a marker of microvascular disease. Persistent UAE greater than 20 μg/min represents a twentyfold greater risk for the development of clinically overt renal disease in patients with type 1 and type 2 diabetes. Prospective studies have demonstrated that increased UAE precedes and is highly predictive of diabetic nephropathy, end-stage renal disease, cardiovascular mortality, and total mortality in patients with diabetes mellitus.[191,193] The DCCT and UKPDS showed that intensive diabetes therapy can significantly reduce the risk of devel-

opment of increased UAE and overt nephropathy in people with diabetes.[72,280] In addition, increased UAE identifies a group of nondiabetic subjects at increased risk of coronary artery disease.[101,164] Interventions, such as control of blood glucose concentrations and blood pressure, particularly with angiotensin converting enzyme (ACE) inhibitors, slow the rate of decline in renal function.[193]

Methods for Measuring Urinary Albumin Excretion

There is no consensus about how a urine sample should be collected for measuring UAE. Variations in urine flow rate in a person may be corrected by expressing albumin as a ratio to creatinine (i.e., albumin:creatinine). *UAE is increased by physiological factors* (e.g., exercise, posture, and diuresis) and the method of urine collection must be standardized. Samples should not be collected after exertion, in the presence of urinary tract infection, during acute illness, immediately after surgery, or after an acute fluid load. All the following urine samples are currently acceptable: (1) 24-hour collection; (2) overnight (8 to 12 hours, timed) collection; (3) 1- to 2-hour timed collection (in laboratory or clinic); or (4) first morning sample for simultaneous albumin and creatinine measurement. Only results for timed specimens can be reported as mg albumin excreted per hour, but the albumin:creatinine ratio is more practical and convenient for the patient and is the recommended method.[15] A first morning void sample is best because it has a lower within-person variation for the albumin:creatinine ratio than a random urine sample.[241] *At least three separate specimens, collected on different days, should be assayed* because of the high intraindividual variation (CV of 30% to 50%) and diurnal variation (50% to 100% higher during the day). Urine should be stored at 4 °C after collection. Alternatively, 2 mL of 50 g/L sodium azide can be added per 500 mL of urine, but preservatives are not recommended for some assays. Bacterial contamination and glucose have no effect. Specimens are stable for 2 weeks at 4 °C and for at least 5 months at −80 °C. Albumin concentration decreased by 0.27% at −20 °C.[177] Freezing samples has been reported to decrease albumin,[84] but mixing immediately before assay eliminates this effect.

Semiquantitative Assays

A number of semiquantitative assays for screening for increased UAE are available. These test strips, most of which are optimized to read "positive" at a predetermined albumin concentration, have been recommended for screening programs. In view of the wide variability in UAE, it must be borne in mind that a "normal" value does not rule out renal disease. *Because these assays measure albumin concentration, dilute urine may yield a false-negative test result.* Refrigerated urine samples should be allowed to reach at least 10 °C before analysis. Albu Screen and Albu Sure (Cambridge Life Sciences, Cambridge, United Kingdom) detect urinary albumin concentrations exceeding 20 and 30 mg/L, respectively. The assay is a latex agglutination inhibition test. Briefly, one drop of urine is mixed with one drop of goat anti-human albumin, the titer of which is adjusted so that all the antibody-binding sites are occupied at urinary albumin concentrations of 30 mg/L or greater. Excess albumin-binding sites are detected by adding one drop of albumin-coated latex microspheres and rocking for 2 minutes. Albumin concentrations less than 20 mg/L produce agglutination. Microbumintest (Bayer Corp., Tarrytown, N.Y.) uses bromophenol blue in an alkaline matrix to detect albumin concentrations exceeding 40 mg/L. The assay sensitivity for increased urinary albumin as measured by quantitative assays is approximately 95%, but because other proteins are also detected, the specificity is approximately 80%.

Micral (Roche Diagnostics, Indianapolis) uses a monoclonal antialbumin IgG complexed to β-galactosidase. The albumin in the urine binds to the antibody-enzyme conjugate in the test strip. Excess conjugate is retained in a separation zone containing immobilized albumin, and only albumin bound to the antibody-enzyme immunocomplex diffuses to the reaction zone. Here it reacts with a buffered substrate (chlorophenol red galactoside) to produce a red color when the β-galactosidase hydrolyzes galactose. The test strip is dipped into the urine for 5 seconds and the intensity of the color after 5 minutes is proportional to the urinary albumin concentration. Direct visual comparison is made with printed color blocks—yellow, light brown, medium brown, brick red, and burgundy representing 0, 10, 20, 50, and 100 mg/L, respectively. No interference is observed with drugs, glucose, urea, or other proteins. Comparison with a reference method demonstrates a sensitivity and specificity for albumin concentrations greater than 20 mg/L (not for microalbuminuria defined by UAE rate) of approximately 100% and 91%, respectively.[182] The *time that the stick is in contact with the urine and the time of reading are critical.* A modification (Micral II) uses a gold-labeled, instead of an enzyme-labeled, antibody. This enhances the stability, allowing the strip to be read any time from 1 to at least 60 minutes. Urine samples with albumin concentrations greater than 100 to 300 mg/L may be diluted and reassayed. The assigned concentration of the color block is multiplied by the dilution factor to obtain the concentration in the sample. These semiquantitative assays have been *recommended for screening only.* However, published studies reveal sensitivities for detection of increased UAE from 67% to 91%.[241] These low sensitivities limit the value of semiquantitative tests even for screening, and further studies are necessary before the dipstick tests can be recommended as replacements for the quantitative tests.[241]

Quantitative Assays

All the sensitive, specific assays for urine albumin use immunochemistry with antibodies to human albumin. Four

methodologies are available: RIA, ELISA, radial immunodiffusion, and immunoturbidimetry.[184] Each method has advantages and disadvantages, and the choice depends on local experience and technical support. In general, the *methods have similar imprecisions, detection limits, and ranges.* A comparison of these methodologies has been performed.[286] Although dye-binding[253] and protein-precipitation[220] assays have been described, these are insensitive and nonspecific and should not be used.

Radial Immunodiffusion

Radial immunodiffusion has not gained wide acceptance because it requires long incubation and a high level of technical skill and cannot be automated. The antibody is incorporated into an agar gel. Aliquots of samples and calibrators are added to wells and allowed to diffuse into the agar. The antigen-antibody complexes precipitate at equilibrium, and after staining, the distance of migration is measured.

Radioimmunoassay

Standard RIA methods have been described[298] with ^{125}I-labeled albumin and antialbumin antiserum, but reagents are radioactive and have a short shelf life. Commercial kits are available.

Enzyme-Linked Immunosorbent Assay

Both competitive and "sandwich" ELISAs are available.[58,277] Although the competitive ELISA is faster because it uses only one incubation with an antibody, it is reported to be less sensitive and exhibits large imprecision. ELISA can be performed on a microplate reader, allowing semiautomation. In the sandwich assay, the primary antibody (antialbumin antiserum) is fixed on the plastic plate, which is then washed. Samples, controls, and calibrators are added, and the complexes detected and quantified by a second antibody conjugated to an enzyme label.

An ELISA method is described in the Evolve site that accompanies this book.

Immunoturbidimetry

Albumin in the urine sample forms an insoluble complex with antibodies to human albumin. PEG accelerates complex formation. The turbidity caused by the complexes is measured by a spectrophotometer at 340 nm and is a measure of albumin concentration. The background absorbance of the initial urine sample is subtracted automatically. This method is simple and less expensive than RIA, and rapid analysis of large numbers of samples is possible. The assays may be performed as either kinetic or equilibrium reactions. Kits are commer-cially available for use on automated analyzers (Roche Diagnostics).

An immunoturbidimetric method for urinary albumin is described in the Evolve site that accompanies this book.

Reference Intervals

URINARY ALBUMIN EXCRETION

	µg/min	mg/24 hr	Corrected (mg/g Urine Creatinine)
Normal	<20	<30	<30
Increased UAE	20-200	30-300	30-300
Clinical albuminuria*	>200	>300	>300

*Also termed "overt nephropathy."

The ADA position statement[15] recommends initial UAE measurement in type 1 diabetes patients who have had diabetes more than or equal to 5 years and in all type 2 diabetic patients. Because of the difficulty in dating the onset of type 2 diabetes, screening should commence at diagnosis. Analysis should be performed annually in all patients who have a negative screening result. Screening may be performed with a semiquantitative assay. If the screening result is positive, UAE should be evaluated by a quantitative assay. Diagnosis requires the demonstration of increased UAE in at least two of three tests measured within a 6-month period.

If the confirmatory test result is positive, treatment with an ACE inhibitor or angiotensin-receptor blocker should be initiated. ACE inhibitors delay the progression to overt nephropathy, and the National Kidney Foundation recommends their use in both normotensive and hypertensive type 1 and 2 diabetic patients.[32] The role of monitoring UAE in patients on ACE inhibitor therapy is less clear, although many experts recommend continued surveillance.[15] Untreated, the UAE would increase 10% to 30% per year, whereas the albumin : creatinine ratio in patients on ACE inhibitors should stabilize or decrease by up to 50%.

INBORN ERRORS OF CARBOHYDRATE METABOLISM

Deficiency or absence of an enzyme that participates in carbohydrate metabolism may result in accumulation of monosaccharides, which can be measured in the urine (see Table 25-1 and Figure 25-9). Most of these conditions are inherited as autosomal recessive traits. Sugars frequently appear in the urine as a result of excessive consumption without underlying disease.

DISORDERS OF GALACTOSE METABOLISM

Galactose is derived from milk in the diet. It resembles glucose in structure, but the hydroxyl group on the fourth carbon has a different spatial arrangement (see Figure 25-2). A deficiency of any of the enzymes that participate in the conversion of galactose to glucose results in *galactosemia.*

Galactose-1-Phosphate Uridyl Transferase Deficiency

Infants with this deficiency fail to thrive on milk because half of the milk sugar, lactose, is galactose. Within a few days of milk ingestion, neonates manifest vomiting and diarrhea. Failure to thrive, liver disease, cataracts, and mental retardation develop later. Hypoglycemia may occasionally develop. The diagnosis should be considered when *the urine demonstrates the presence of a reducing substance that does not react in a glucose oxidase test.* Early detection and treatment (withholding galactose from the diet) are necessary to prevent irreversible changes. Because other reducing sugars may give similar results, galactose should be identified by paper chromatography (discussed later). Diagnosis is suggested by detecting galactose and galactose-1-phosphate in blood and confirmed by directly assaying red blood cell transferase activity. A spot test is also available.

Uridine Diphosphate Galactose-4-Epimerase Deficiency

This extremely rare disorder exhibits clinical findings similar to transferase deficiency.

Galactokinase Deficiency

This is a milder condition manifested predominantly by cataracts caused by galactitol deposits in the lens. The diagnosis is confirmed by demonstrating normal transferase activity and no galactokinase in red blood cells.

Disorders of Fructose Metabolism

Fructose may appear in the urine after eating fruits, honey, and syrups, but has no significance in these circumstances. Three disorders of fructose metabolism, inherited as autosomal recessive traits, produce fructosuria.

Essential Fructosuria

This rare and harmless defect is due to a lack of *fructokinase.*

Hereditary Fructose Intolerance

A *deficiency of fructose-1-phosphate aldolase* produces this rare disorder with hypoglycemia and liver failure. Fructose ingestion inhibits glycogenolysis and gluconeogenesis, producing hypoglycemia. Early detection is important because this condition responds to a diet devoid of sucrose and fructose.

Hereditary Fructose-1,6-Diphosphatase Deficiency

Patients with this deficiency have episodes of apnea and hyperventilation and hypoglycemia, ketosis, and lactic acidosis caused by severe impairment of gluconeogenesis. Diagnosis is by demonstrating the enzyme defect in liver biopsy specimens.

Disorders of Pentose Metabolism

Alimentary Pentosuria

Pentoses may be present in the urine after eating large quantities of fruits such as cherries, plums, or prunes.

Essential Pentosuria

This is a harmless inborn error caused by a *deficiency of* L-*xylulose reductase,* an enzyme involved in the glucuronic acid pathway.

Other Urinary Sugars

Lactose is sometimes detected in the urine of women during lactation and occasionally toward the end of pregnancy. Patients with *lactase deficiency,* a common disorder caused by a congenital or acquired deficiency of intestinal lactase, exhibit abdominal pain, diarrhea, and lactose in the urine.

Maltose has rarely been detected in the urine of some patients.

Many *reducing substances* other than sugars may be found in urine (Box 25-6). Ascorbic acid (vitamin C) may be ingested in large quantities or may be present in antibiotic preparations administered intravenously. In either case, excess concentrations usually appear in the urine and contribute significantly to the total reducing substances present.

Methods for Measuring Individual Sugars

Qualitative Tests for Glucose

Techniques for separating and identifying sugars have included fermentation, optical rotation, osazone formation with phenylhydrazine, specific chemical tests, and paper or thin-layer chromatography. The availability of glucose oxidase test strips, specific for glucose, has greatly simplified the differentiation of glucose from other reducing substances. For practical purposes, the *urinary sugars of clinical interest are glucose and galactose.* Urine from infants and children should be tested routinely by both the glucose oxidase and copper reduction tests to identify individuals with inborn errors of metabolism. Reducing substances other than glucose should be further identified by chromatographic procedures.

Qualitative Tests for Urinary Sugars Other Than Glucose

Fructose (Selivanoff's Test)

Hot HCl converts fructose to hydroxymethyl furfural (HMF), which links with *resorcinol* to produce a red compound. To make the reagent, dissolve 50 mg of resorcinol in 33 mL of concentrated HCl and dilute to 100 mL with water. Add 0.5 mL of urine to 5 mL of reagent in a test tube and bring to a boil. Fructose produces a red reaction within 30 seconds. The test is sensitive to 100 mg fructose per dL, provided there is no excess glucose. A 2-g/dL solution of glucose produces about the same color as 100 mg/dL of fructose after 30 seconds of boiling. A solution of fructose (0.5 g/dL) should be used as a control. With high concentrations of fructose, a red precipitate forms.

Pentoses (Bial's Test)

By heating with HCl, pentoses are converted to furfural, which reacts with orcinol to form green compounds. Dissolve 300 mg of orcinol in 100 mL of concentrated HCl and

add 0.25 mL of ferric chloride solution (10 g/dL). Glucose, if present in the urine, should be removed by fermentation with yeast. Add 0.5 mL of urine to 5 mL of reagent in a test tube and bring to a boil. Pentoses produce a green reaction. The detection limit of the test is 100 mg pentose per dL. A solution of xylose (0.5 g/dL) should be used as a control. Glucuronates produce a similar color if the boiling is prolonged. As with Selivanoff's reagent, fructose produces a red reaction.

Identification of Urinary Sugars by Paper Chromatography

Sugars can be separated by ascending or descending chromatography on paper and located after color development with dinitrosalicylic acid. The variable rates of migration depend on the solubility of the sugars in the particular solvent system. Presumptive identification is made by comparison of the migration (R_f) value of the unknown with those of reference compounds. One procedure may be performed conveniently in a 6 × 18-inch Pyrex jar with a tightly fitting cover.

This method for identifying urinary sugars by paper chromatography is described in the Evolve site that accompanies this book.

Identification of Urinary Sugars by Thin-Layer Chromatography

Identification of urine sugars can also be made by using thin-layer chromatographic techniques as described by Young and Jackson.[302] When frequent chromatographic separations are necessary, this method is preferred over paper chromatography because of the shorter time required. If such studies are performed infrequently, paper chromatography is simple, is adequate for most separations, and requires little actual working time.

GLYCOGEN STORAGE DISEASE

Glycogen, although present in most tissue, is stored principally in the liver and skeletal muscle. During fasting, liver glycogen is converted to glucose to provide energy for the whole body. In contrast, skeletal muscle lacks glucose-6-phosphatase, and muscle glycogen can be used only locally for energy. *Glycogen storage disease* is a generic name encompassing at least 10 rare inherited disorders of glycogen storage in tissue (Table 25-1). The different forms of glycogen storage disease are categorized by numerical type in the chronological sequence in which these defects were identified. Each form is due to a deficiency of a specific enzyme in glycogen metabolism, producing either a quantitative or qualitative defect of glycogen storage. Because the liver and skeletal muscle have the highest rates of glycogen metabolism, these are the structures most affected. The liver forms (types I, III, IV, and VI) are marked by *hepatomegaly* (caused by increased liver glycogen stores) and *hypoglycemia* (caused by the inability to convert glycogen to glucose). The hypoglycemia is manifested by autonomic clinical symptoms (sweating, shakiness, and lightheaded feeling), growth retardation, and laboratory findings of decreased insulin and increased glucagon concentrations in the blood. The muscle forms (types II, IIIA, V, and VII), in contrast, have mild symptoms that *usually appear in young adulthood during strenuous exercise* owing to the inability to provide energy for muscle contraction. Other muscle disorders may exhibit similar symptoms but can be readily differentiated by evaluating glycogen stores. The specific diagnosis of each type is made directly by *demonstrating the enzyme defect in tissue.* A very brief overview is provided here; for a more detailed description, readers should consult Chen and Burchell.[57]

Type I (Glucose-6-Phosphatase Deficiency)

Type I is the most common and severe form (also called *von Gierke's disease*), and patients have accumulation of glycogen of normal chemical structure in the liver. The disease is characterized by massive hepatomegaly, growth retardation, fasting hypoglycemia, increased lactic acid concentrations in the blood (caused by excessive glycolysis), hyperuricemia (caused by competitive inhibition by lactate of renal tubular urate secretion and increased uric acid production), and hypertriglyceridemia (increased lipolysis caused by decreased glucose). Glucagon and epinephrine do not produce hyperglycemia but result in increased lactate concentrations. The failure of blood glucose to increase in response to galactose administration (oral or intravenous) is diagnostic. Galactose is normally converted to glucose (see Figure 25-9), but in these patients glucose-6-phosphate cannot be hydrolyzed to glucose. Treatment includes partaking of frequent meals and nasogastric feeding at night to maintain blood glucose concentrations. Glucose-6-phosphatase activity can be assayed in a liver biopsy. A variant of the disease, type IB, has been identified as a defect in the glucose-6-phosphatase transport system. Other forms include a defect in microsomal phosphate or pyrophosphate transport (type IC) and a defect in microsomal glucose transport (type ID).

Individuals with type I glycogen storage disease (von Gierke's) exhibit decreased availability of liver glycogen demonstrated by a decreased or absent blood glucose response to epinephrine administration. An assay based on this phenomenon is known as the "epinephrine tolerance test." With it an intramuscular injection of 1 mL of a 1/1000 (1-g/L) solution of epinephrine hydrochloride is given, and blood samples are taken at 30, 45, 60, 90, and 120 minutes. Normal people increase blood glucose by 35 to 45 mg/dL in 40 to 60 minutes, with a return to the fasting concentration by 2 hours. The test is rarely used because the diagnosis of von Gierke's disease is made by a failure to increase blood glucose in response to galactose administration, with confirmation by direct assay of glucose-6-phosphatase activity.

Type II (Acid α-Glucosidase Deficiency)

Type II affects predominantly the heart and skeletal muscle, producing muscle weakness and cardiomegaly. Liver function is normal and patients do not have hypoglycemia. Two forms are identified: (1) infantile (*Pompe disease*), which presents in the first few months of life with symptoms of weakness and respiratory difficulties and usually evolves to death caused by cardiac failure within 1 year; and (2) a juvenile form that is milder and may present in the second or third decade of life with difficulty in walking. The diagnosis is made by measuring α-glucosidase activity in muscle, liver, or leukocytes.

Type III (Amylo-1,6-Glucosidase Deficiency)

Deficiency of glycogen debranching enzyme results in storage of an abnormal form of glycogen (limit dextrinosis). Both the liver and muscle are usually affected (type IIIA), producing hepatomegaly and muscle weakness. Approximately 15% of patients have only liver involvement, without apparent muscle disease (type IIIB). Clinical and biochemical features resemble those of type I disease. Differentiation from type I is by a hyperglycemic response to galactose, lower concentrations of urate and lactate in the blood, and elevated serum transaminase and creatine kinase activities. Enzyme deficiency can be demonstrated in muscle or liver and occasionally in erythrocytes.

Type IV (Branching Enzyme Deficiency)

Type IV is an extremely rare disorder manifested by production of an abnormal form of unbranched glycogen in all tissue. Patients exhibit hepatosplenomegaly with ascites and liver failure. Abnormal glycogen can be identified in the tissue and muscles; leukocytes or cultured fibroblasts can be used to demonstrate the enzyme deficiency.

Type V (Muscle Phosphorylase Deficiency)

Type V, also called *McArdle's disease,* usually presents in the second or third decade with muscle cramps after exercise. Moderate exercise can be sustained, and patients have a "second wind," when symptoms disappear if exercise is continued. Increased plasma creatine kinase activities at rest, the failure of ischemic exercise to increase serum lactate concentrations while producing an exaggerated increase in ammonia, myoglobinuria, and diminished activity of muscle phosphorylase establish the diagnosis. Patients respond to oral glucose administration or injections of glucagon.

Type VI (Liver Phosphorylase or Phosphorylase Kinase Deficiency)

Type VI is a heterogeneous group of diseases arising from a deficiency of liver phosphorylase or one of the subunits of phosphorylase kinase. It is a rare and relatively benign disorder manifested as hepatomegaly caused by increased deposits of normal glycogen in the liver. Diagnosis is made by measuring enzyme activity in the liver or in red or white blood cells.

Type VII (Muscle Phosphofructokinase Deficiency)

Patients with this rare type have deposits of abnormal glycogen in muscle. Exercise intolerance, unresponsiveness to glucose administration, and hemolysis (caused by decreased glycolysis in erythrocytes) are noted clinically, producing hyperbilirubinemia, pigmenturia, and reticulocytosis. The specific enzyme defect can be demonstrated.

CHAPTER 26

Lipids, Lipoproteins, Apolipoproteins, and Other Cardiovascular Risk Factors*

Nader Rifai, Ph.D.,
and G. Russell Warnick, M.S., M.B.A.

Lipids are ubiquitous in the body tissue and have an important role in virtually all aspects of life—serving as hormones or hormone precursors, aiding in digestion, providing energy storage and metabolic fuels, acting as functional and structural components in cell membranes, and forming insulation to allow nerve conduction or to prevent heat loss. In this chapter we have categorized lipids into basic lipids, lipoproteins, and apolipoproteins. We discuss the basic biochemistry, clinical significance, and analytical considerations of each.

BASIC BIOCHEMISTRY

For many years, much attention has been focused on certain lipids and the lipoproteins that transport them in the circulation, mainly because of their strong association with coronary heart disease (CHD). Therefore the use of the term *lipids* in clinical chemistry and laboratory medicine has become virtually synonymous with lipoprotein metabolism and atherosclerosis, a cause of CHD. Much of this association has been recognized through the conduct of large national and international collaborative analytical, epidemiological, and clinical studies. In the early 1980s, findings from the Coronary Primary Prevention Trial demonstrated that a decrease in plasma cholesterol concentration results in a reduction in the incidence of CHD. Since that time, several secondary prevention trials using diet or drugs to lower blood cholesterol have also demonstrated a reduction in cardiovascular death and atherosclerotic clinical events. Based on these trials and other evidence, the National Heart, Lung, and Blood Institute established the National Cholesterol Education Program (NCEP) to increase public awareness about cholesterol; devise strategies for diagnosis and treatment of hypercholesterolemia in adults, children, and adolescents; and improve the laboratory measurement of lipids. The European Atherosclerosis Society and other individual countries have also established similar programs to address these issues.

Basic Lipids

The term *lipid* applies to a class of compounds that are soluble in organic solvents and nearly insoluble in water. Chemically, lipids are either compounds that yield fatty acids on hydrolysis or complex alcohols that combine with fatty acids to form esters. Some lipids are more complex, containing nonlipid groups, such as sialic, phosphoryl, amino,

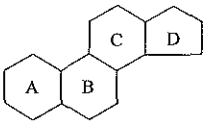
*The authors gratefully acknowledge the contribution by Drs. John Albers and Paul Bachorik on which portions of this chapter are based. Additional portions have been adapted from Rifai N, Kwiterovich PO Jr. Disorders of lipid and lipoprotein metabolism in children and adolescents. In Soldin SJ, Rifai N, Hick JMB eds. Biochemical basis of pediatric diseases, 3rd ed. Washington DC: AACC Press, 1998.

BOX 26-1 Classification of Clinically Important Lipids

Sterol Derivatives
- Cholesterol and cholesteryl esters
- Steroid hormones
- Bile acids
- Vitamin D

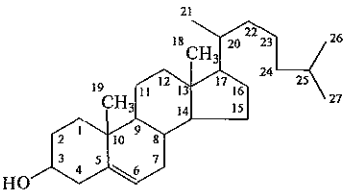
Fatty Acids
- Short chain (2-4 carbon atoms)
- Medium chain (6-10 carbon atoms)
- Long chain (12-26 carbon atoms)
- Prostaglandins

Glycerol Esters
- Tri-, di-, and monoglycerides (acylglycerols)
- Phosphoglycerides



Sphingosine Derivatives
- Sphingomyelin
- Glycosphingolipids

Terpenes (Isoprene Polymers)
- Vitamin A
- Vitamin E
- Vitamin K



or sulfate groups. The presence of these groups gives them the property (amphipathic) of having an affinity for both water and organic solvents, which is important in the formation of membranes. Lipids have been broadly subdivided into five groups based on their chemical structure (Box 26-1).

Cholesterol

Although every living organism has been found to contain sterols, cholesterol is found almost exclusively in animals, in which it is also the main sterol. Virtually all cells and body fluids contain some cholesterol. Like other sterols, cholesterol is a solid alcohol of high molecular weight and possesses the tetracyclic perhydrocyclopentanophenanthrene skeleton. The molecule contains 27 carbon atoms, numbered as shown in Figure 26-1. Knowledge of this sterane skeleton and numbering system is important not only to clinical laboratorians but to practicing clinicians because cholesterol is the initial starting point in many metabolic pathways. These include vitamin D synthesis (see Chapter 49), steroid hormone synthesis (see Chapter 51), and bile acid metabolism. Because the enzymes modifying the sterane ring or its radicals in each metabolic pathway are known by both their site and type of reaction (e.g., 21-hydroxylase in cortisol synthesis), the diagnosis of many disease states consequently depends on isolating the site of enzyme dysfunction (e.g., 21-hydroxylase deficiency in adrenogenital syndrome).

Perhydrocyclopentanophenanthrene (sterane) skeleton

Cholesterol

Figure 26-1 Structure of cholesterol.

Cholesterol Absorption

Cholesterol is presented to the intestinal wall from three sources: the diet, bile and intestinal secretions, and cells. Animal products—especially meat, egg yolk, seafood, and whole-fat dairy products—provide the bulk of dietary cholesterol. Although cholesterol intake varies considerably according to the dietary intake of animal products, the average American diet is estimated to contain approximately 300 to 450 mg of cholesterol per day. A similar amount of cholesterol is present in the gut from biliary secretion and the turnover of mucosal cells. Practically all cholesterol in the intestine is present in the unesterified (free) form. Esterified cholesterol in the diet is rapidly hydrolyzed in the intestine to free cholesterol and free fatty acids by cholesterol esterases secreted from the pancreas and small intestine.

To be absorbed, unesterified cholesterol must first be solubilized. This occurs through the formation of mixed micelles that contain unesterified cholesterol, fatty acids, monoglycerides (derived from triglycerides), phospholipids (lysolecithin), and conjugated bile acids. Formation of mixed micelles aids cholesterol absorption by both solubilizing the cholesterol and facilitating its transport to the surface of the luminal cell, where it is absorbed. Because of their amphipathic properties, the bile acids act as detergents and are the most important factor affecting micelle formation. In the absence of bile acids, digestion and absorption of both cholesterol and triglyceride are severely impaired. The quantity of dietary cholesterol that can be absorbed appears to depend on the amount that can be solubilized by micelles. On the average, 30% to 60% of dietary and intestinal cholesterol is absorbed daily. With increments in dietary cholesterol, additional cholesterol is absorbed to a maximum of approximately 1 g/day when oral intake reaches 3 g/day. The ability of cholesterol to form micelles is also influenced by the quantity of dietary fat but not its degree of saturation. Increased amounts of fat in the diet result in expansion of mixed micelles, which in turn allows for more cholesterol to be solubilized and absorbed. Most cholesterol absorption

occurs in the small intestine (middle and terminal ileum), and as absorption of fat and cholesterol occurs in the small intestine, the micelles break up, thus reducing further cholesterol absorption.

In addition to animal cholesterol, approximately 200 to 300 mg of plant sterols are ingested daily. The most common plant sterol is β-sitosterol. Plant sterols differ from cholesterol only by small variations on the sterol side chain. Despite their close similarity to cholesterol, plant sterols are poorly absorbed. When plant sterols are administered in amounts of 5 to 15 g/day, they significantly inhibit the absorption of cholesterol. Although the mechanism for reducing cholesterol absorption has not been determined, plant sterols have been used therapeutically in patients with elevated plasma cholesterol levels.

After its absorption into the intestinal mucosal cell, cholesterol, together with triglycerides, phospholipids, and a number of specific apoproteins, is assembled into a large lipoprotein called the *chylomicron* (see later section on lipoprotein metabolism, exogenous pathway). One apoprotein component known as apolipoprotein (apo) B-48 is vital to the formation of chylomicrons, and in people with a rare deficiency of apo B-48 synthesis, chylomicron formation, and consequently cholesterol and fat absorption, is severely impaired. Chylomicrons enter the lymphatics, which empty into the thoracic duct and eventually enter the systemic venous circulation at the junction of the left subclavian vein and left internal jugular vein.

Cholesterol Synthesis

Of the total cholesterol synthesized daily, about 300 to 1000 mg is derived from dietary intake. Cholesterol is also synthesized endogenously by the liver and other tissue from simple molecules, particularly acetate. Knowledge of the endogenous cholesterol synthetic pathway has assumed great significance in the past decade because agents have been sought to suppress or decrease endogenous cholesterol synthesis. The necessity for clinical medicine to understand the fundamental biochemistry of this pathway was underscored by the triparanol disaster of 1960. Triparanol is a drug that inhibits the final step in the endogenous cholesterol synthetic path (conversion of desmosterol to cholesterol), but does not inhibit the rate-limiting enzyme of cholesterol synthesis, 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA) reductase (Figure 26-2). When triparanol was used to treat hypercholesterolemia, the drug caused tissue accumulation of desmosterol, resulting in the development of cataracts, alopecia, and atherosclerosis in treated patients. Drugs such as atorvastatin, lovastatin, mevastatin, pravastatin, and simvastatin selectively suppress the rate-limiting enzyme HMG-CoA reductase, and thereby lower serum cholesterol levels significantly without the accumulation of water-insoluble intermediates of cholesterol synthesis, such as desmosterol.

Although essentially all cells have the capacity to synthesize cholesterol from acetyl-CoA, almost 90% of synthesis occurs in the liver and gut; peripheral cells and other organs depend on cholesterol delivery from the circulation. Cholesterol biosynthesis is best conceptualized as occurring in three stages (Figures 26-2 through 26-4). In the first stage, acetyl-CoA, a key metabolic intermediate derived from carbohydrates, amino acids, and fatty acids, forms the six-carbon thioester HMG-CoA. In the second stage, HMG-CoA is reduced to mevalonate, then decarboxylated to five-carbon isoprene units. These isoprene units are condensed to form first a 10-carbon (geranyl pyrophosphate) and then a 15-carbon intermediate (farnesyl pyrophosphate). Two of these C_{15} molecules combine to produce the final product of the second stage—squalene, a 30-carbon acyclic hydrocarbon. The second stage is important because it contains the step involving the microsomal enzyme HMG-CoA reductase, which is the rate-limiting enzyme in cholesterol biosynthesis. The enzyme that forms farnesyl pyrophosphate, geranyl transferase, is an important second site of regulation in cholesterol synthesis, and inhibition at this level permits the formation of physiologically important intermediate isoprenoids in the absence of cholesterol synthesis. The third and final stage of synthesis occurs in the endoplasmic reticulum, with many of the intermediate products being bound to a specific carrier protein. Squalene, after an initial oxidation, undergoes cyclization to form the 4-ring, 30-carbon intermediate, lanosterol. In a series of oxidation-decarboxylation reactions, a number of side chains are removed from the pentanophenanthrene structure to form the 27-carbon molecule of cholesterol.

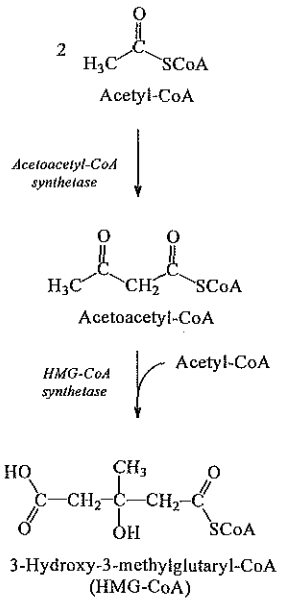


Figure 26-2 Cholesterol biosynthesis (stage I).

Cholesterol Esterification

Once synthesized, cholesterol is released into the circulation in the form of lipoprotein, primarily very low-density lipoprotein (VLDL; see later section on lipoprotein metab-

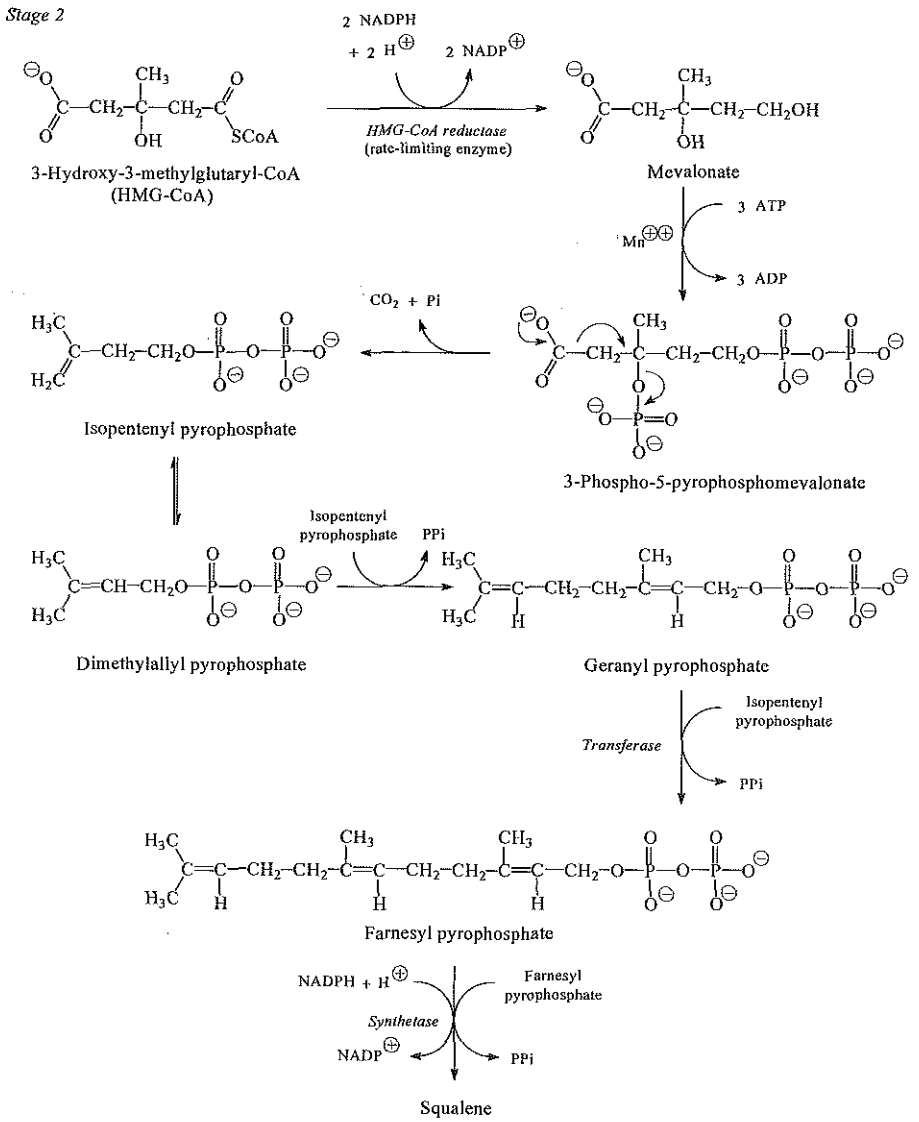

Figure 26-3 Cholesterol biosynthesis (stage 2).

olism, endogenous pathway). The major apoprotein found in VLDL is apo B-100, a protein related to apo B-48, which is found in chylomicrons. Esterification is important because it serves to enhance the lipid-carrying capacity of the lipoprotein in plasma and prevent intracellular toxicity by free cholesterol. The reaction is catalyzed by lecithin-cholesterol acyltransferase (LCAT) in the plasma and acyl-cholesterol acyltransferase (ACAT) within the cell. The intracellular ACAT pathway is the major pathway in the liver, intestine, adrenal cortex, and probably in the arterial wall. This is an energy-requiring pathway, and the initial reaction (Figure 26-5) involves activation of a fatty acid with thio coenzyme A (Co ASH) to form an acyl-CoA, which in turn reacts with cholesterol to form an ester. The LCAT reaction does not require CoASH and results from fatty acid transfer from the second carbon position of lecithin to cholesterol (see Figure 26-5). Cholesteryl esters account for about 70% of the cholesterol in plasma, and LCAT is responsible for the formation of virtually all of this cholesteryl ester. LCAT is synthesized in the liver, released into the circulation, and primarily activated by apo A-I (see later section on apolipoproteins).

Plasma LCAT activity may have some significance analytically because the enzyme continues to esterify plasma cholesterol even after the blood sample is drawn and stored at room temperature. If it is necessary to distinguish between esterified and unesterified cholesterol, analysis should be carried out as soon as possible, or the samples should be cooled to at least 4 °C or frozen, preferably at –70 °C or lower.

Cholesterol Catabolism

Once lipoprotein cholesterol enters the cell, the cholesteryl esters are hydrolyzed by lysosomal acid lipase. The lack or malfunction of this enzyme results in intracellular accumulation of cholesterol esters and produces a clinical disorder known as *cholesteryl ester storage disease.*

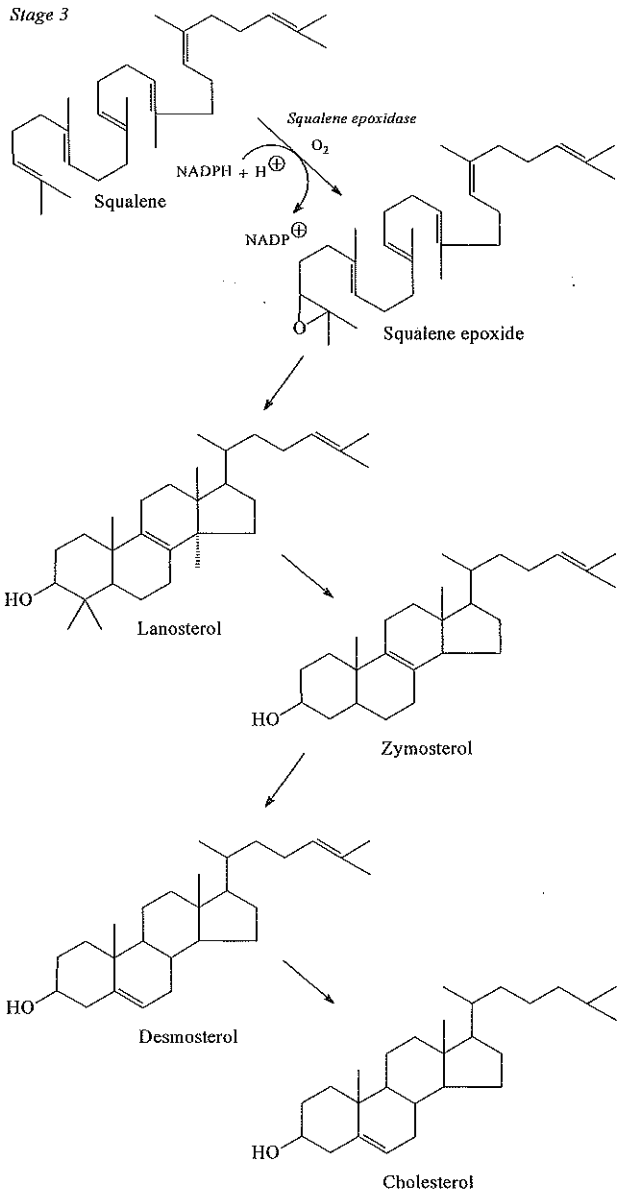

Figure 26-4 Cholesterol biosynthesis (stage 3).

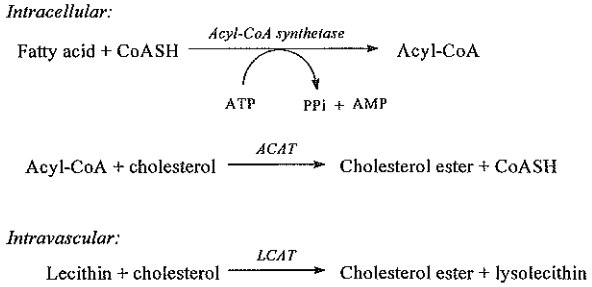

Figure 26-5 Intracellular and intravascular esterification of cholesterol mediated by ACAT and LCAT, respectively.

Cholesterol reaching the liver is either secreted unchanged into bile or metabolized to bile acids. Approximately one third of the daily production of cholesterol, or about 400 mg/day, is converted into bile acids (Figure 26-6). The conversion of cholesterol to cholic and chenodeoxycholic acids, the major bile acids in humans, involves the shortening of the cholesterol side chain and hydroxylation of the sterol nucleus. The first step, which is also the rate-limiting step, is the hydroxylation of the 7-position of the sterol nucleus, catalyzed by the enzyme 7α-hydroxylase (see Figure 26-6). The bile acids are then conjugated with either glycine or taurine and enter the bile canaliculi. After reaching the small intestine, the conjugated bile acids play an active part in cholesterol and fat absorption, as discussed previously. Some of the bile acids are deconjugated and converted by bacteria in the intestine to secondary bile acids. Cholic acid is converted to deoxycholic acid, and chenodeoxycholic acid is metabolized to lithocholic acid. About 90% of the bile acids, except lithocholic, are reabsorbed in the lower third of the ileum and returned to the liver by the portal vein, thus completing the enterohepatic circulation (see also Chapter 47).

A significant amount of cholesterol is also excreted directly into the biliary system, where it is solubilized to form mixed micelles with bile acids and phospholipids. If the amount of cholesterol in bile exceeds the capacity of these solubilizing agents, however, excess cholesterol can precipitate, forming cholesterol gallstones. In westernized societies, approximately 80% of all gallstones are cholesterol-containing stones.

Fatty Acids

The fatty acids are one of the simpler molecular forms of lipids. They are generically indicated by the chemical formula RCOOH, where "R" stands for an alkyl chain. Fatty acid chain lengths vary and are commonly classified according to the number of carbon atoms present. Three somewhat arbitrarily defined groups of fatty acids are those containing 2 to 4 carbon atoms (short chain), 6 to 10 carbon atoms (medium chain), and 12 to 26 carbon atoms (long chain). Those of importance in human nutrition and metabolism are of the long-chain class containing an even number of carbon atoms.

Fatty acids are further classified according to their degree of saturation. Saturated fatty acids have no double bonds between carbon atoms, monounsaturated fatty acids contain one double bond, and polyunsaturated fatty acids contain more than one double bond (Figure 26-7). The double bonds in polyunsaturated fatty acids of both animal and plant origin are usually 3 carbon atoms apart. Some oils from marine fish living in deep, cold waters (e.g., salmon) possess numerous (up to 6) unsaturated bonds and are usually more than 20 carbon atoms long. These oils can be easily oxidated because of their high degree of unsaturation.

The labeling of the carbon atoms in fatty acids can be either from the carboxyl terminal (Δ-numbering system) or from the methyl terminal (η- or ω-numbering system;

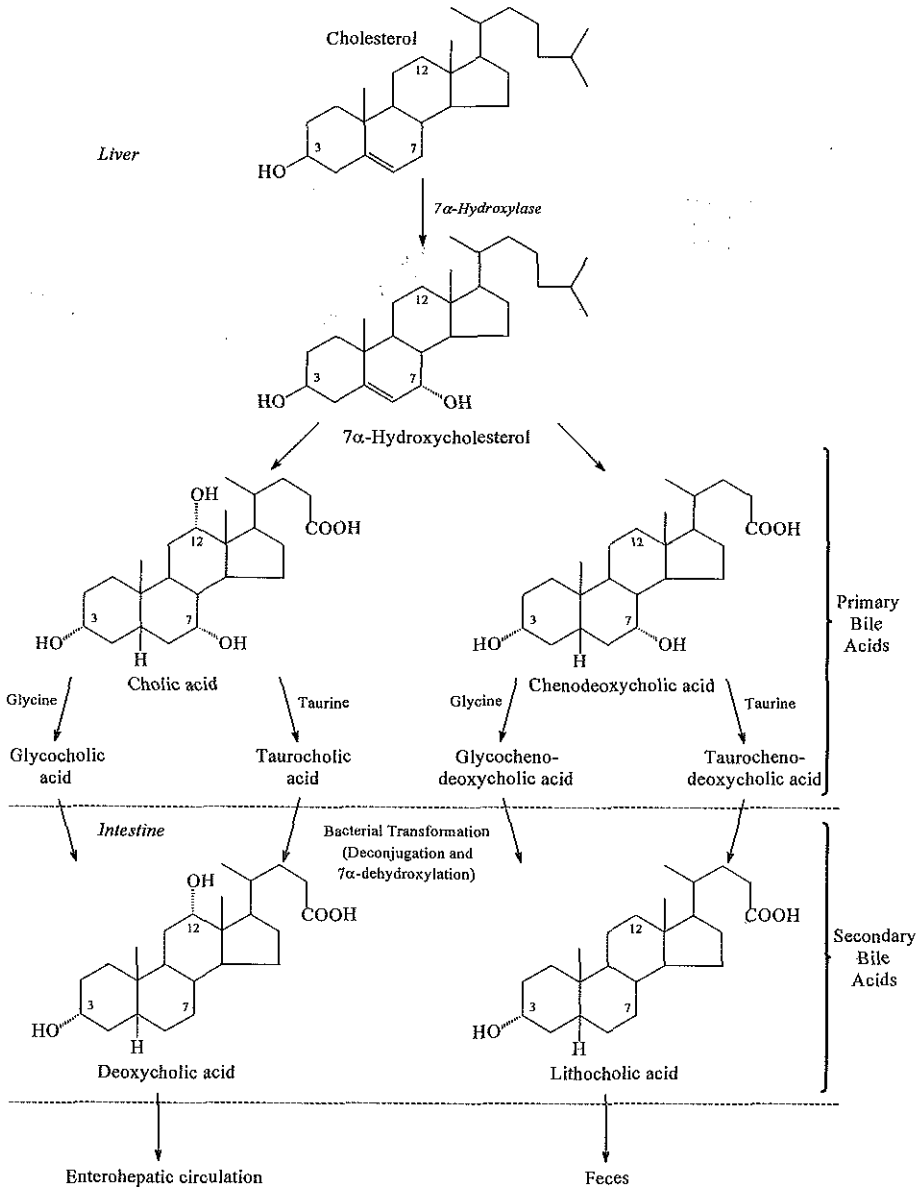

Figure 26-6 Bile acid synthesis.

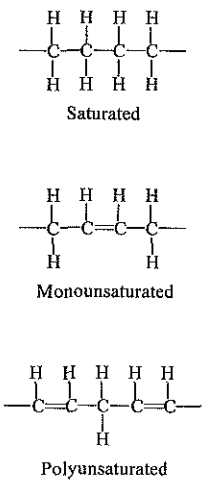

Figure 26-7 Saturated and unsaturated fatty acids.

Table 26-1). In addition, the carbon atoms may be labeled with Greek symbols, with α being adjacent to the carboxyl group and ω being farthest away. In the Δ-system, fatty acids are abbreviated according to the number of carbon atoms, the number of double bonds, and the position(s) of double bond(s). For example, linoleic acid, which contains 18 carbons and two unsaturated bonds between carbons 9 and 10 and between carbons 12 and 13, could be written as $C_{18}:2^{9,12}$. Using the η- or ω-system, linoleic acid would be abbreviated to $C_{18}:2n-6$, where only the first carbon forming the unsaturated pair is written. The *Geneva* or *systematic* classification is a third system of nomenclature (Table 26-1).

In saturated fatty acids, the chain is extended and flexible (i.e., the carbon atoms rotate freely around the longitudinal axis). Unsaturated fatty acids, however, have fixed 30° bends

TABLE 26-1 Fatty Acids Commonly Found in Human Tissue

Common Name	Systematic Name	Δ-Numbering	η-(ω) Numbering
Lauric	Dodecanoic	12:0	12:0
Myristic	Tetradecanoic	14:0	14:0
Palmitic	Hexadecanoic	16:0	16:0
Palmitoleic	9-Hexadecenoic	$16:1^{9}$	16:1n-7
Stearic	Octadecanoic	18:0	18:0
Oleic	9-Octadecenoic	$18:1^{9}$	18:1n-9

Linolenic*	9,12,15-Octadecatrienoic	$18:3^{9,12,15}$	18:3n-3
Arachidic	Eicosanoic	20:0	20:0
Arachidonic	5,8,11,14-Eicosatetraenoic	$20:4^{5,8,11,14}$	20:4n-6

*Essential fatty acids.

in their chains at each double bond. Depending on the plane in which this bend occurs, either the *cis* or *trans* isomer is produced. In mammals, all naturally occurring unsaturated fatty acids are of the *cis* variety. *Trans* fatty acids result from catalytic hydrogenation, a process used to "harden" fats in the manufacture of certain foods, such as margarine. Most fats in the human body are derived from the diet, which on the average contains up to 40% fat, 90% of which is triglyceride. In addition, humans can synthesize most fatty acids, including saturated, monounsaturated, and some polyunsaturated fats. However, some fatty acids cannot be synthesized. One such fatty acid is linoleic acid ($C_{18}:2^{9,12}$), which is found only in plants. Because it is vital for health and growth and development, it is termed an *essential fatty acid.* Linoleic acid is converted to arachidonic acid, which has an important role in prostaglandin synthesis and perhaps in myelinization of the central nervous system.

The fatty acid carboxyl group has a pK_a of approximately 4.8; thus free fatty acid molecules in both plasma and intracellular fluid (pH of 7.4 and 7.0, respectively) exist in an ionized form. Much of the fatty acid in plasma exists as either esters with cholesterol or glycerol or is transported as a fatty acid–albumin complex or fatty acid–prealbumin complex. One molecule of albumin can carry as many as 20 molecules of fatty acid. The normal level of free fatty acids in human blood is 0.30 to 1.10 mmol/L, or about 8 to 31 mg/dL of plasma. The flux of free fatty acids through the plasma is very large and quite sensitive to physiological energy demands (exercise and physical work), the level of blood glucose, and psychological stresses that cause liberation of epinephrine.

Fatty Acid Catabolism

Long-chain fatty acids are oxidized in the mitochondria and produce energy by a series of reactions that operate in a repetitive manner to shorten the fatty acid chain by two carbon atoms at a time from the —COOH terminal of the molecule, a process known as β-oxidation. For example, 1 mole of C_{16} fatty acid is converted to 8 moles of acetyl-CoA. Acetyl-CoA does not normally accumulate in the cell but is enzymatically condensed with oxaloacetate, derived largely from carbohydrate metabolism (Figure 26-8), to give citrate, which is a major component of the tricarboxylic acid cycle (Krebs cycle). The Krebs cycle serves as a common pathway for the final oxidation of nearly all food material, whether derived from carbohydrate, fat, or protein. It is important to bear in mind that the smooth operation of the Krebs cycle depends on the availability of sufficient oxaloacetate to serve as an acceptor for acetyl-CoA.

The complete oxidation of a single fatty acid molecule produces a large quantity of energy. For example, the complete oxidation of 1 mole of palmitic acid to carbon dioxide and water produces 16 moles of CO_2, 16 moles of H_2O, and 129 moles of adenosine triphosphate (ATP), or 2340 Cal.* Thus the standard free energy for oxidation of palmitic acid is 2340 Cal, whereas the free energy liberated by hydrolysis of 129 moles of ATP is 940 Cal, indicating that the efficiency of energy conservation in fatty acid oxidation is approximately 40% under standard conditions.

By means of suitable enzyme reactions, the chemical energy stored in fatty acids can be released for metabolic processes or stored in the form of high-energy compounds, such as ATP. Triglycerides that contain three fatty acid molecules, therefore, are an efficient storage form for metabolic energy. The amount of energy produced by metabolizing 1 mole of palmitic acid (16 carbon atoms) is approximately twice that produced by metabolizing an equivalent amount (2.5 mol) of glucose (6 carbon atoms per molecule). Carbohydrate storage requires water for hydration; triglyceride storage does not. In addition to their high intrinsic energy content, triglycerides have a low density (<1 g/mL) and, because of their hydrophobic nature and peripheral distribution in the body, provide excellent insulation.

*The unit used in discussing the energy value of food is the Calorie (Cal), equal to 1000 calories or 1 kilocalorie (kcal). In the SI system, the unit of energy is the joule (J), and 1 calorie = 4.1868 J.

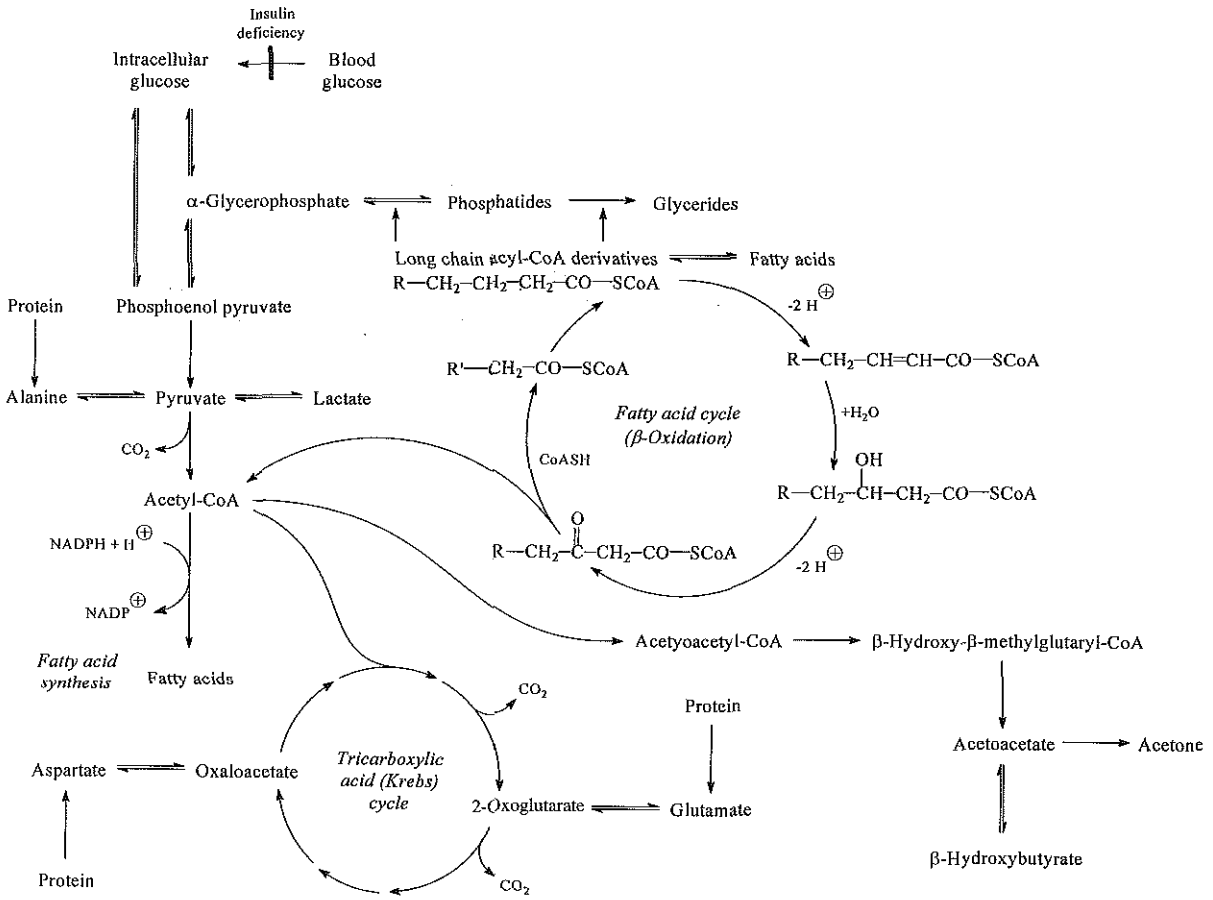

Figure 26-8 Metabolic relations among intermediates of carbohydrate, fat, and protein metabolism. Note that acetyl-CoA is produced from both carbohydrate and fat. The glucogenic amino acids, derived from protein metabolism, enter glycolytic paths as α-keto acids. Ketogenic amino acids enter as acetyl-CoA.

Ketone Formation

During prolonged starvation or when carbohydrate metabolism is severely impaired, as in uncontrolled diabetes mellitus (see Chapter 25), the formation of acetyl-CoA exceeds the supply of oxaloacetate. The abundance of acetyl-CoA results from excessive mobilization of fatty acids from adipose tissue and excessive degradation of the fatty acids by β-oxidation in the liver. The resulting acetyl-CoA excess is diverted to an alternative pathway in the mitochondria and forms acetoacetic acid, β-hydroxybutyric acid, and acetone—three compounds known collectively as *ketone bodies* (Figure 26-9). The presence of ketone bodies is a frequent finding in severe, uncontrolled diabetes mellitus.

As shown in Figure 26-9, the first product, acetoacetyl-CoA, condenses in the mitochondria with a third molecule of acetyl-CoA to yield HMG-CoA. This pool of HMG-CoA is distinct from that in the cytosol that is an intermediate in cholesterol synthesis. The HMG-CoA produced in the mitochondria is then cleaved enzymatically to yield acetoacetate and acetyl-CoA. Some of the acetoacetate formed in liver cells is usually reduced to β-hydroxybutyrate. Because acetoacetate is unstable, a further portion decomposes to form carbon dioxide and acetone, the third ketone body found in severe, untreated diabetes mellitus. Ketosis, therefore, develops from excessive production of acetyl-CoA because the body attempts to obtain necessary energy from stored fat in the absence of an adequate supply of carbohydrate metabolites (see Chapter 25).

Inadequate incorporation of acetyl-CoA into the Krebs cycle may be further aggravated by inhibition of the oxaloacetate-generating enzyme system by excess accumulation of palmitic-CoA and other long-chain fatty acid–CoA derivatives in the liver. Skeletal muscle and heart (and brain in prolonged fasting) use ketone bodies by resynthesizing their CoA derivatives of the acids and subsequently oxidizing them for the production of energy. Although liver cells are largely responsible for converting fatty acids, they cannot metabolize acetoacetate, because liver lacks 3-ketoacid CoA transferase, the enzyme required for transferring CoA from succinyl-CoA.

The entire process of ketosis reversed by restoring an adequate level of carbohydrate metabolism. In starvation, restoration consists of adequate carbohydrate ingestion; in diabetes mellitus, ketosis can be reversed by insulin administration, which permits circulating blood glucose to be taken up by the cells. With production of oxaloacetate, the

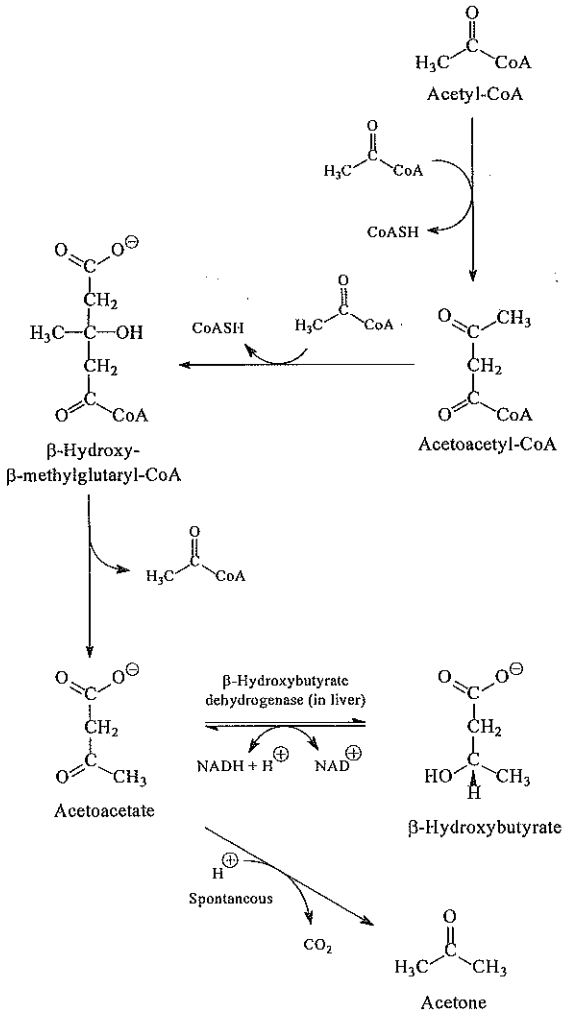

Figure 26-9 Formation of ketone bodies.

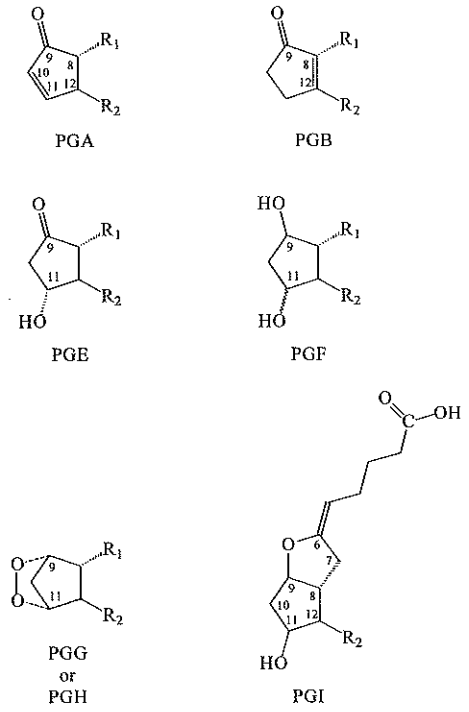

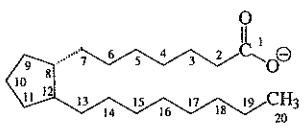

Figure 26-10 Major prostaglandin classes (series). R_1 and R_2 are prostaglandin side chains.

acceptor of acetyl-CoA, normal metabolism is restored, and the release of fatty acids from adipose tissue slows and is finally reversed. A graphic view of these metabolic reactions is outlined in Figure 26-8, which shows the interrelationship between carbohydrate, fatty acid, and protein metabolism.

Prostaglandins

Prostaglandins and related compounds are derivatives of fatty acids, primarily arachidonate. The group consists of prostaglandins, thromboxanes, some hydroperoxy- and hydroxy–fatty acid derivatives, and leukotrienes. Although their full physiological role is not completely known, they exert diverse biological actions. They are extremely potent, producing physiological actions at concentrations as low as 1 μg/L.

The prostaglandins are a series of C_{20} unsaturated fatty acids containing a cyclopentane ring; the parent fatty acid has been given the trivial name *prostanoic acid.* The seven-carbon chain linked to C-8 of prostanoic acid (R_1) projects below the plane of the ring, whereas the eight-carbon chain attached to C-12 (R_2) projects above the ring.

By convention, prostaglandins are abbreviated *PG,* with the class designated by a capital letter (A, B, E, F, G, H, and I), followed by a number and then in some cases a Greek letter (Figure 26-10). With the exception of PGG and PGH, which have the same ring structure (cyclopentane endoperoxide), the letters refer to different ring structures. PGA and PGB have keto groups at C-9, with the A series having a double bond between C-10 and C-11 and the B series having a double bond between C-8 and C-12. PGE also has a C-9 keto bond but a hydroxyl group at C-11. The F series has hydroxyl groups at both C-9 and C-11. The difference between PGG and PGH, which have identical ring structures, occurs in the side chain at C-15 in R_2; the G series has a peroxide group, whereas the H series has a hydroxyl group. The I series has a double-ring formation, C-9 of the cyclopentane ring being linked to C-6 of the side chain by an oxygen molecule to form a second five-sided ring (see Figure 26-10). The endoperoxide PGs (G and H series) are intermediates in the formation of other PGs, such as the A, B, E, F, and I series.

The number after the capital letter is usually written as a subscript and is used to designate the number of unsaturated bonds in the PG side chains and not within the ring structure itself. In PGE_1, for example, a double bond exists between C-13 and C-14; in the 2 series (PGE_2), a double bond exists between C-13 and C-14 and between C-5 and

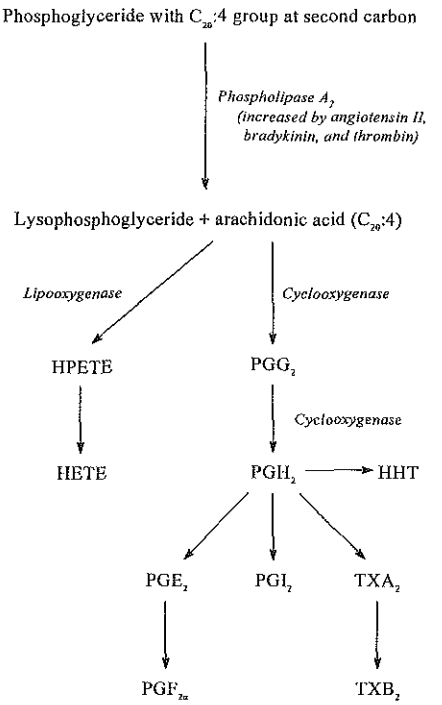
TABLE 26-2 Naturally Occurring Prostaglandins (PG)

Primary PG	Other PG
PGE_1	PGA_1
$PGF_{1\alpha}$	PGA_2
PGE_2	$19\alpha\text{-OHPGA}_1$
$PGF_{2\alpha}$	$19\alpha\text{-OHPGA}_2$
PGG_2	PGB_1
PGH_2	PGB_2
PGI_2	$19\alpha\text{-OHPGB}_2$
Thromboxane A_2	PGE_3
Thromboxane B_2	$PGF_{3\alpha}$

C-6; and in the 3 series (PGE_3), an additional double bond occurs between C-17 and C-18. The 2 series is most common. The bond between C-13 and C-14 is always *trans*, whereas those between C-5 and C-6 and between C-17 and C-18 are always *cis*. At C-15, all naturally occurring prostaglandins have a hydroxyl group that projects below the plane of the ring. The use of the Greek letter (α or β) applies only to the F series and refers to the hydroxyl group found at C-9. In the α-series, the hydroxyl group projects below the ring plane in the same direction as the C-11 hydroxyl group, whereas the β-series denotes that the hydroxyl at C-9 is above the plane of the ring. Sixteen naturally occurring prostaglandins have been described (Table 26-2), but only seven, along with two thromboxanes, are commonly found throughout the body. These are termed the *primary prostaglandins.*

Although prostaglandins appear hormonelike in action, they are different from hormones in that (1) they are synthesized at the site of action and (2) they are made in almost all tissue. Linoleic acid ($C_{18}:2^{9,12}$) is the precursor of two of the three 20-carbon fatty acids that form prostaglandins; linolenic acid ($C_{18}:2^{9,12,15}$) is the other precursor. Both of these fatty acids are considered essential because they cannot be synthesized in the body and therefore must be present in the diet (see Chapter 48). The three C_{20} fatty acids subsequently formed are $C_{20}:3^{5,8,11}$ (eicosatrienoic acid), $C_{20}:4^{5,8,11,14}$ (eicosatetraenoic or arachidonic acid), and $C_{20}:5^{8,11,14,17}$(eicosatrienoic acid). These three fatty acids form the PG_1, PG_2, and PG_3 series, respectively.

Once formed, prostaglandins exert very short-lived effects and are rapidly catabolized (their half-life is expressed in seconds). Inactivation of prostaglandin appears to be mediated by two enzymes, 15 α-hydroxy-prostaglandin dehydrogenase and Δ^{13}-prostaglandin reductase. Prostaglandins are not stored; instead, the precursor C_{20} fatty acids are present in tissue attached to the C-2 (see later section in this chapter on glycerol esters) of phosphoglycerides. When necessary, the C_{20} precursor is hydrolyzed by phospholipase A_2, which is specific for the C-2 atom of the phosphoglyceride. The release of the C_{20} fatty acid appears



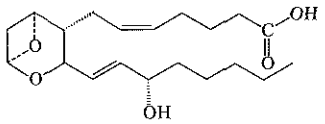


Figure 26-11 Synthesis of prostaglandins from arachidonic precursor. *PG,* Prostaglandin; *TX,* thromboxane; *HPETE, HETE, HHT,* 12-l-hydroxy-5,8,10-heptadecatrienoic acid.

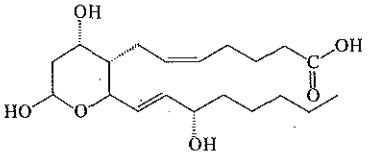


to be the rate-limiting step in prostaglandin synthesis and is stimulated by the effect of bradykinin, thrombins, or angiotensin II.

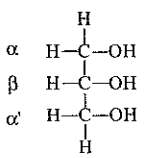
Although it is probable that all prostaglandins follow a similar synthetic pathway, C_{20}:4 (arachidonic acid) has been the most intensively studied and is used to illustrate the pathway (Figure 26-11). Once released, arachidonic acid follows one of two pathways. The lipoxygenase route produces 12-L-hydroperoxy-5,8,10,14 eicosatetraenoic acid (HPETE); HPETE spontaneously decomposes to 12-L-hydroxy-5,8,10,14 eicosatetraenoic acid (HETE). The alternative pathway is mediated by cyclooxygenase (COX) to produce the endoperoxides PGG_2 and PGH_2. The latter can be degraded to 12-L-hydroxy-5,8,10-heptadecatrienoic acid. What controls the entry into a specific pathway remains speculative; however, it is known that nonsteroidal antiinflammatory drugs ([NSAIDs]: aspirin, ibuprofen, and indomethacin) inhibit the COXs, thereby decreasing prostaglandin synthesis. Two isoforms of COX are known, COX-1 and COX-2. COX-1 levels are in general rather constant in cells, whereas COX-2 is synthesized in response to inflammation. Certain drugs that inhibit both COXs have nephrotoxic and ulcerogenic side effects. Therefore newer NSAIDs are being tested to preferentially inhibit COX-2 to reduce side effects while maintaining the desirable antiinflammatory therapy.

Prostaglandin I_2, or prostacyclin, is derived from arachidonic acid (see Figure 26-11) in the vascular endothelium. It has a powerful vasodilatory action, especially on the coro-

Thromboxane A_2 (TXA_2)

Thromboxane B_2 (TXB_2)

Figure 26-12 Structures of thromboxanes.



nary arteries, and is also responsible for inhibiting platelet aggregation. Thromboxane A_2 is synthesized from arachidonic acid but is also produced by platelets. It has the opposite effect of prostacyclin (i.e., it stimulates the contraction of arterial smooth muscle and enhances platelet aggregation). It has a very short half-life, about 30 seconds, and is rapidly converted to its inactive metabolite, thromboxane B_2. The thromboxanes are slightly different from the other prostaglandins in that they contain six-sided rings of five carbon atoms and one oxygen atom (Figure 26-12). Table 26-3 lists some of the reported functions of the various prostaglandins. With increasing knowledge of the physiological role of the prostaglandins, it is likely that discrete disorders of prostaglandin metabolism will be discovered and that prostaglandins, prostaglandin analogues, or prostaglandin antagonists will be used in clinical practice.

TABLE 26-3 Prostaglandin-Mediated Effects

Site of Action	Physiological Response
Arterial smooth muscle	Alters blood pressure
Uterine muscle	Induces labor, therapeutic abortion
Lower gastrointestinal tract	Increases motility
Bronchial smooth muscle	Bronchospasm
Platelets	Increases coagulability
Capillaries	Increases permeability
Stomach	Enhances gastric acid secretion
Adipose tissue	Inhibits triglyceride lipolysis

Glycerol Esters (Acylglycerols)

Virtually all the complex lipids are fatty acid derivatives, and in most cases they are covalently linked to an alcohol. One of the most common alcohols found in human metabolism is glycerol, a three-carbon molecule containing three hydroxyl groups.

The two terminal carbon atoms in the molecule are chemically equivalent and are designated α and α′. The center carbon is labeled β. A common alternative labeling system uses the numeral 1 for the α-carbon, 2 for the β-carbon, and 3 for the α′-carbon.

The class of acylglycerol (glyceride) is determined by the number of fatty acyl groups present; one fatty acid, monoacylglycerols (monoglycerides); two fatty acids, diacylglycerols (diglycerides); three fatty acids, triacylglycerols (triglycerides). In a monoacylglycerol, the fatty acid may be linked to any of the three carbon atoms. By convention, the number system is used to indicate the carbon position (e.g., 1-monoglyceride indicates a fatty acid attachment to the α-carbon). This numbering system applies to all acylglycerols, including the phosphoglycerides, as shown later. Diglycerides are either 1,2- or 1,3-diglycerides (Figure 26-13).

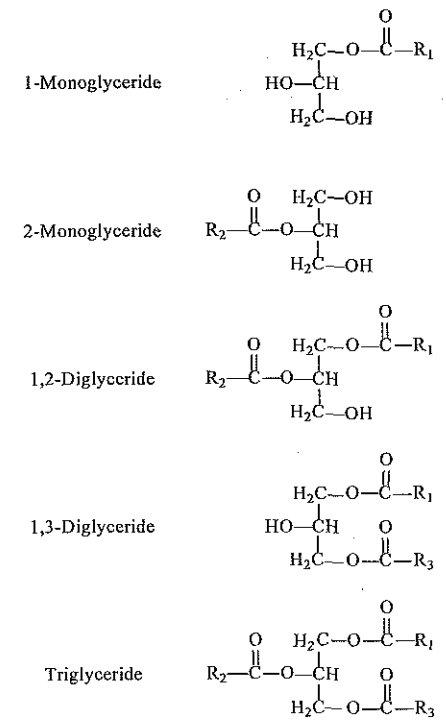


Figure 26-13 Structure and classification of glycerol esters (acylglycerols). R_1, R_2, and R_3 are fatty acid(s) of varying chain length.

In human nutrition, triglycerides are the most prevalent glycerol esters encountered and constitute 95% of tissue storage fat and are the predominant form of glyceryl ester found in plasma. The fatty acid residues found in monoglycerides, diglycerides, or triglycerides vary considerably

and usually include combinations of the long-chain fatty acids, shown in Table 26-1. Triglycerides from plants (e.g., corn, sunflower seed, and safflower oils) tend to have large amounts of C_{18}:2 or linoleic residues and are liquid at room temperature. Triglycerides from animals, especially ruminants, tend to have C_{12}:0 through C_{18}:0 fatty acid residues (saturated fats) and are solids at room temperature. Some plant triglycerides, such as coconut oil, are highly saturated and may be solid at room temperature.

Triglycerides are digested in the duodenum and proximal ileum. Through the action of pancreatic and intestinal lipases and in the presence of bile acids, they are hydrolyzed to glycerol, monoglycerides, and fatty acids. After absorption, triglycerides are resynthesized in the intestinal epithelial cells and combined with cholesterol and apo B-48 to form chylomicrons. Chylomicrons are then secreted to the lymphatic system, travel through the thoracic duct, and eventually reach the bloodstream through the jugular vein.

Another major class of glycerol esters consists of those containing phosphoric acid at the third (α′) carbon atom; these esters are called phosphoglycerides (Figure 26-14). In their simplest form, the A group is an H atom and the molecule is therefore a diacylphosphoglyceride. Usually, however, the A is an alcohol-derived group, such as choline, serine, inositol, or ethanolamine (see Figure 26-14). If A is choline, the molecule is referred to as *phosphatidylcholine;* if it is ethanolamine, it will be referred to as *phosphatidylethanolamine,* etc. Phosphatidylcholines have also been collectively referred to as the *lecithins,* whereas phosphatidylethanolamine, phosphatidylserine, and phosphatidylinositol have been called the cephalins. As the fatty acid residues (R_1 and R_2 in Figure 26-14) vary, several different lecithins and cephalins are formed. These phosphoglycerides are named according to the fatty acid acyl ester attached at C-1 and C-2 of the glycerol. The saturated fatty acid attaches to the C-1, whereas (poly)unsaturated fatty acid attaches primarily at C-2. Phosphatidylcholine is the precursor of the potent lipid mediator, platelet-activating factor.

In inner mitochondrial membranes, more complex phosphoglycerides known as *cardiolipins* can be found. They are derived from two phosphoglyceride molecules joined by a glycerol bridge.

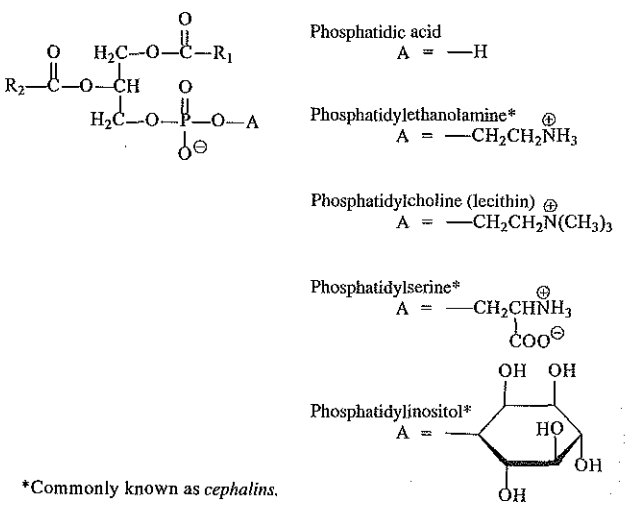

Figure 26-14 Structures of phosphoglycerides and common alcohol groups associated with them. R_1 and R_2 are fatty acid(s) of varying carbon atom lengths.

Sphingolipids

Sphingolipids are a fourth class of lipids found in humans and are derived from the amino alcohol sphingosine (Figure 26-15). This dihydric 18-carbon alcohol contains an amino group at C-17. A fatty acid containing 18 or more carbon atoms can be bound to the amino group through an amide

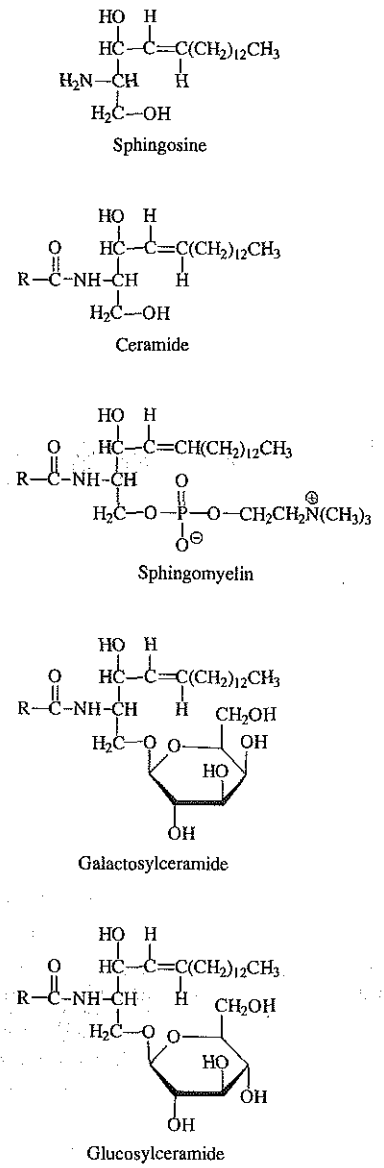

Figure 26-15 Structures of sphingolipids.

linkage to form *ceramide*. This is the intermediary step in the formation of three important sphingolipids: sphingomyelin, galactosylceramide, and glucosylceramide (see Figure 26-15). The sugar-containing ceramides can have a sulfate group attached (usually to the 2-position of the galactose residue) to form the sulfatides. The glycosyl ceramides can also have additional monosaccharide moieties (such as galactose, *N*-acetylgalactosamine, and *N*-acetylneuraminic acid) to form complex globosides and gangliosides. These complex sphingolipids form the major lipids of cell membranes and the central nervous system. Gangliosides are particularly prevalent in the gray matter of the brain, whereas membrane glycosphingolipids have a major role in cellular interactions, growth, and development, and have been a source of blood group and tumor antigens.

Terpenes

Terpenes are polymers of the five-carbon isoprene unit and include vitamins A, E, and K (see Chapter 30) and the dolichols, which play an important role in protein glycation.

LIPOPROTEINS

Lipids synthesized in the liver and the intestine have to be transported to the various tissues to accomplish their metabolic functions. Because of their insolubility, they are transported in the plasma in macromolecular complexes called lipoproteins. Lipoproteins are spherical particles with nonpolar lipids (triglycerides and cholesterol esters) in their core and more polar lipids (phospholipids and free cholesterol) oriented near the surface. They also contain one or more specific proteins, called apolipoproteins, that are located on their surfaces (Figure 26-16).[255] The association of the core lipids with the phospholipid and protein coat is noncovalent, occurring primarily through hydrogen bonding and van der Waals forces. This binding of lipid to protein is loose enough to allow the ready exchange of lipids among the plasma lipoproteins and between cell membranes and lipoprotein, yet strong enough to allow the various classes and subclasses of lipoprotein to be isolated by a variety of analytical techniques.

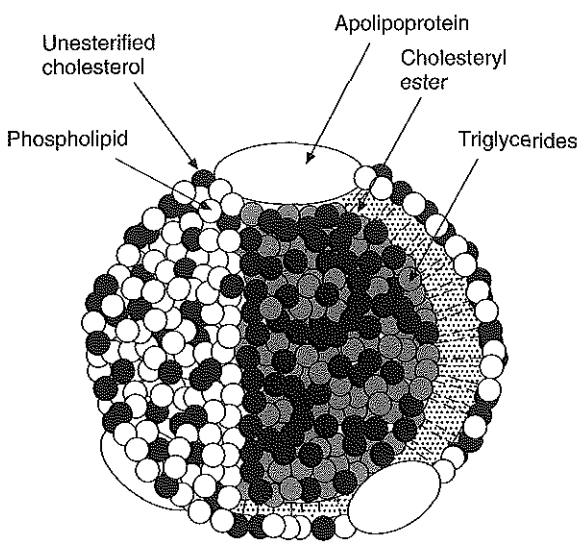

Figure 26-16 Structure of a typical lipoprotein particle.

Lipoproteins have different physical and chemical properties (Table 26-4) as they contain different proportions of lipids and proteins (Table 26-5). Historically, lipoproteins have been categorized based on differences in their hydrated densities as determined by ultracentrifugation. These categories include (1) chylomicrons, (2) VLDL, (3) intermediate-density lipoprotein (IDL), (4) low-density lipoprotein (LDL), (5) high-density lipoprotein (HDL), and (6) lipoprotein(a) [Lp(a)]. HDL is further divided by density into two subpopulations, HDL_2 and HDL_3. As discussed later in this chapter, the two subfractions of HDL seem to differ in their metabolic roles and clinical significance. Lp(a) is a distinct class of lipoprotein (see Table 26-4) that is structurally related to LDL, because both lipoprotein classes possess one molecule of apo B-100 per particle and have similar lipid compositions.[71,173] However, unlike LDL, Lp(a) contains a carbohydrate-rich protein [apo(a)] that is covalently bound to the apo B-100 through a disulfide linkage. The available evidence suggest that Lp(a) contains one molecule of apo(a) and one molecule of apo B-100 per Lp(a) particle. Apo(a) is the unique protein component of Lp(a) and exhibits a significant sequence homology with plasminogen and a high degree of variation in polypeptide chain length. Apo(a) is composed of a serine protease domain and a kringle-containing domain (Figure 26-17). Unlike plasminogen, however, Lp(a) is not activated to form an active protease. The kringle that is contiguous with the protease domain, kringle 5, shares 85% amino acid homology with plasminogen kringle 5, whereas the kringle 4 domain has 78% to 88% amino acid homology with kringle 4 of plasminogen. Apo(a) contains 10 distinct classes of kringle 4–like domains that differ from each other in amino acid sequence. Kringle 4 type 1 and kringle 4 types 3 to 10 are present as a single copy on apo(a) particles. In contrast, kringle 4 type 2 is present in variable number of repeats (3 to >40) and therefore is primarily responsible for the size heterogeneity of apo(a) and consequently of Lp(a) (see Figure 26-17).[150,312]

In the fasting state, most plasma triglycerides are present in VLDL. In the nonfasting state, chylomicrons appear transiently and contribute significantly to the total plasma triglyceride level. LDL carries about 70% of total plasma cholesterol but very little triglyceride (see Table 26-5). HDL contains about 20% to 30% of plasma cholesterol.

Lipoproteins also are separated by electrophoresis on agarose, cellulose acetate, and paper, and polyacrylamide gels.[214] At a pH of 8.6, HDL migrates with the α-globulins, LDL with the β-globulins, and VLDL and Lp(a) between the α- and β-globulins, in the pre-β-globulins region. IDL forms a broad band between β- and pre-β-globulins. Chylomicrons remain at the point of application. The lipoproteins have

been referred to by their electrophoretic locations pre-β-lipoprotein, VLDL; β-lipoprotein, LDL; and α-lipoprotein, HDL.

APOLIPOPROTEINS

Apolipoproteins are the protein components of lipoprotein. The characteristics and main known functions of the major apolipoproteins are summarized in Table 26-6.[167,255] Each class of lipoprotein has a variety of apolipoproteins in differing proportions, with the exception of LDL, which contains only apo B-100. Apo A-I is the major protein in HDL. Apo C-I, C-II, C-III, and E are present in various proportions in all lipoproteins except LDL. Apolipoproteins collectively have three major physiological functions. They are involved in (1) activating important enzymes in the lipoprotein metabolic pathways, (2) maintaining the structural integrity of the lipoprotein complex, and (3) facilitating the uptake of lipoprotein into cells through their recognition by specific cell surface receptors.[167]

Apolipoprotein A

Apolipoprotein A-I and apo A-II constitute about 90% of total HDL protein. The ratio of apo A-I to A-II in HDL is about 3:1.[31] In addition to being an important structural

component of HDL, apo A-I is a cofactor for LCAT, the enzyme responsible for forming cholesteryl esters in plasma. Some evidence suggests that apo A-II may inhibit LCAT and activate hepatic triglyceride lipase. Apo A-IV is a component of newly secreted chylomicrons, but is not a major constituent of chylomicron remnants, VLDL, LDL, and HDL. The primary function of apo A-IV is currently unknown, but it has been shown to activate LCAT in vitro,[45] and available data suggest it plays a role in the transport of cholesterol from peripheral tissue to the liver.

Apolipoprotein B

Apolipoprotein B exists in two forms: apo B-100 and apo B-48.[167] The two proteins are known to be translation products of a single structural gene. Apo B-100, a single polypeptide of more than 4500 amino acids, is the full-length translation product of the apo B gene. In humans, apo B-100 is made in the liver and secreted into plasma as part of VLDL. Apo B-100 is the major apolipoprotein of LDL, the end product of VLDL catabolism. Each VLDL particle contains one molecule of apo B-100. In the fasting state, most of the apo B in plasma is apo B-100. Unlike the other apolipoproteins, however, apo B-100 cannot move from one lipoprotein particle to another, and VLDL apo B-100 remains with the lipoprotein as it is catabolized to LDL. Apo B-48 contains 2152 amino acids and is identical to the amino-terminal portion of apo B-100. Apo B-48 results from the posttranscriptional modification of internal apo B-100 messenger ribonucleic acid (mRNA), in which a single base substitution produces a stop codon corresponding to residue 2153 of apo B-100. Apo B-48 is made in the intestine and is the major apo B component of chylomicrons. Both apo B-100 and apo B-48 play important roles in the secretion of VLDL and chylomicrons, respectively. Apo B-100 is recognized by the LDL receptor in hepatic and peripheral tissues and allows the LDL receptor-mediated internalization of LDL[34] (see later sections on lipoprotein metabolism, endogenous and exogenous pathways).

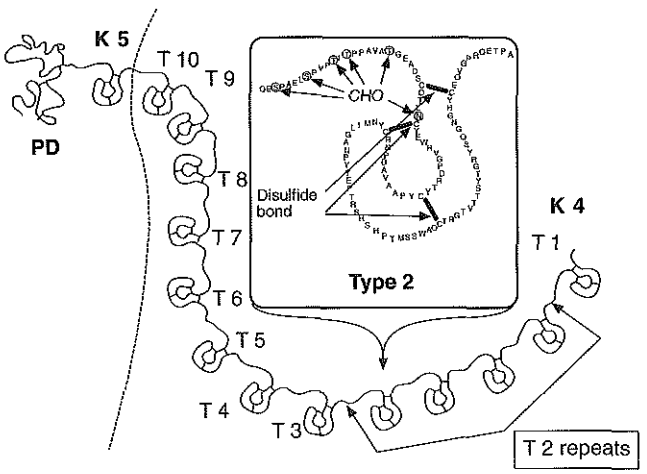

Figure 26-17 Structure of lipoprotein(a).

Apolipoprotein C

Apolipoproteins C-I, C-II, and C-III are associated with all lipoproteins except LDL. Apo C-I, the smallest of the C apolipoproteins, has been reported to activate LCAT in vitro. Apo C-II plays an important role in the metabolism of triglyceride-rich lipoprotein (VLDL and chylomicrons)

TABLE 26-6 Classification and Properties of Major Human Plasma Apolipoproteins

Apolipoprotein	Molecular Weight (Da)	Chromosomal Location	Function	Lipoprotein Carrier(s)
Apo A-I	29,016	11	Cofactor LCAT	Chylomicron, HDL
Apo A-II	17,414	1	Not known	HDL

by activating lipoprotein lipase (LPL), an enzyme that hydrolyzes lipoprotein triglycerides. Because of differences in sialic acid content, apo C-III exists in at least three polymorphic forms.[36] The precise metabolic function of apo C-III is unknown, but it may inhibit LPL and activate LCAT, and therefore may regulate the activities of these enzymes.

Apolipoprotein E

Apolipoprotein E is a 34-kDa plasma glycoprotein that is found primarily in chylomicrons, VLDL, HDL, and chylomicron and VLDL remnants. Removal of apo E–bearing lipoproteins is mediated by several different cellular receptors that recognize a cluster of positively charged amino acids in a specific region of apo E. Apo E plays a central role in the metabolism of chylomicrons and VLDL remnants. It regulates and facilitates lipoprotein uptake in the liver through (1) interaction of chylomicron remnants with chylomicron remnant receptors, and (2) binding of VLDL remnants to the LDL (B, E) receptor.[167]

There are three common apo E isoforms, designated E_2, E_3, and E_4, that were initially distinguished by isoelectric-focusing electrophoresis.[329] These isoforms have amino acid substitutions at residues 112 and 158.[234] Apo E_2 has cysteine residues in both positions and apo E_4 has arginine residues in both positions, whereas apo E_3 has cysteine and arginine at positions 112 and 158, respectively. Apo E_2 exhibits reduced binding affinity for the B and/or E remnant receptor compared with apo E_3, which can lead to an accumulation of apo E–containing lipoprotein in the circulation, whereas apo E_4–containing lipoproteins are cleared more rapidly than those containing apo E_3. These isoforms are coded for by the three alleles of the apo E gene, ε2, ε3, and ε4. The ε3 allele is most frequent, although the relative proportions of the three alleles vary among populations.[59,61,62] These apo E alleles have been shown to contribute significantly to the variability of LDL cholesterol and apo B-100 levels within populations.[272] Individuals with at least one ε2 allele tend to have lower levels of apo B-100 and LDL cholesterol than do those who are homozygous for the ε3 allele, whereas individuals with at least one ε4 allele tend to have higher levels of those analytes, possibly because of the higher affinity of apo E_4 for the LDL receptor, with consequent interference with LDL clearance from the circulation. Also, variation at the apo E locus may explain some of the differences observed in plasma lipid and lipoprotein between individual responses to dietary and drug therapy.[220]

Lipoprotein Metabolism

The pathways of lipoprotein metabolism are complex.[34,103,255] They include exogenous and endogenous pathways based on whether they carry lipids of dietary or hepatic origin (Figures 26-18 and 26-19) and other pathways such as the

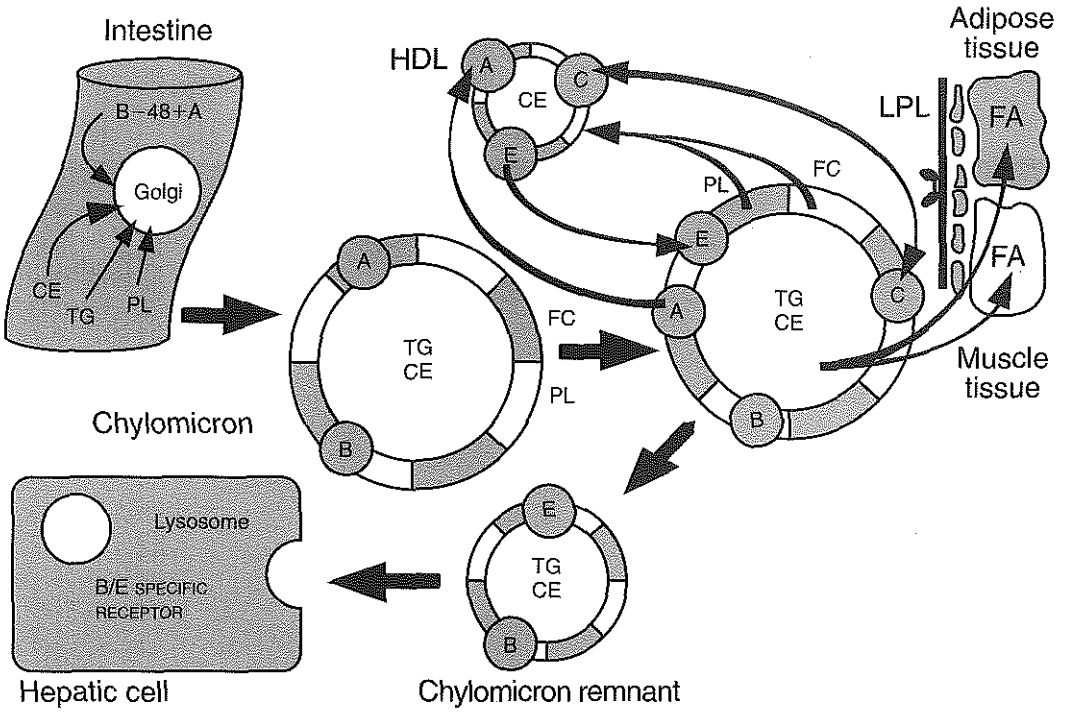

Figure 26-18 Exogenous lipoprotein metabolism pathway. *TG,* Triglyceride; *CE,* cholesterol ester; *FC,* free cholesterol; *PL,* phospholipids; *HDL,* high-density lipoproteins; *FA,* fatty acid; *LPL,* lipoprotein lipase; *B,* apolipoprotein B-48; *A,* apolipoprotein A-I; *C,* apolipoprotein C-II; *E,* apolipoprotein E. *(From Rifai N. intracellular LDL receptor pathway (Figure 26-20) and the HDL reverse cholesterol transport pathway (Figure 26-21). Although these pathways are viewed as functionally distinct, they have overlapping points that provide sites at which dietary lipid intake can influence the synthesis and catabolism of endogenous lipids.

Exogenous Pathway

Nascent chylomicrons are assembled from dietary triglycerides and cholesterol in the enterocytes and packaged in secretory vesicles in the Golgi apparatus. These particles are then transported by exocytosis into the extracellular space and introduced into circulation through the intestinal villi. The lipid content of nascent chylomicrons consists mainly of triglycerides (90% by mass), whereas the protein components include apo B-48 and the A apolipoproteins (2% by mass).[97] Shortly after entering the circulation, these particles acquire the C apolipoproteins and apo E from circulating HDL (see Figure 26-18). Apo C-II, now present on the surface of chylomicrons, activates the LPL attached to the luminal surface of endothelial cells, which rapidly hydrolyzes the triglycerides to free fatty acids. The fatty acids are associated with albumin and can either be taken up by muscle cells as an energy source or into adipose cells for storage. Simultaneously, some of the phospholipids and the apo A apolipoproteins are transferred from the chylomicron particle onto HDL. The newly formed particle, the chylomicron remnant, contains 80% to 90% of the triglyceride content of the original chylomicron. Because of the presence of apo B-48 and apo E on its surface, the chylomicron remnant can be recognized by specific hepatic remnant receptors and internalized by endocytosis. The components of the particle are then hydrolyzed in the lysosomes. The cholesterol released can form bile acids, be incorporated into newly synthesized lipoprotein, or be stored as cholesteryl ester. Furthermore, the cholesterol from these remnants can down regulate HMG-CoA reductase, the rate-limiting enzyme of cholesterol biosynthesis (see earlier section on cholesterol synthesis).

Endogenous Pathway

Hepatocytes have the ability to synthesize triglycerides from carbohydrates and fatty acids. In addition, when dietary cholesterol acquired from the receptor-mediated uptake of chylomicron remnants is insufficient, hepatocytes also synthesize their own cholesterol by increasing the activity of HMG-CoA reductase. The endogenously made triglycerides and cholesterol are packaged in secretory vesicles in the

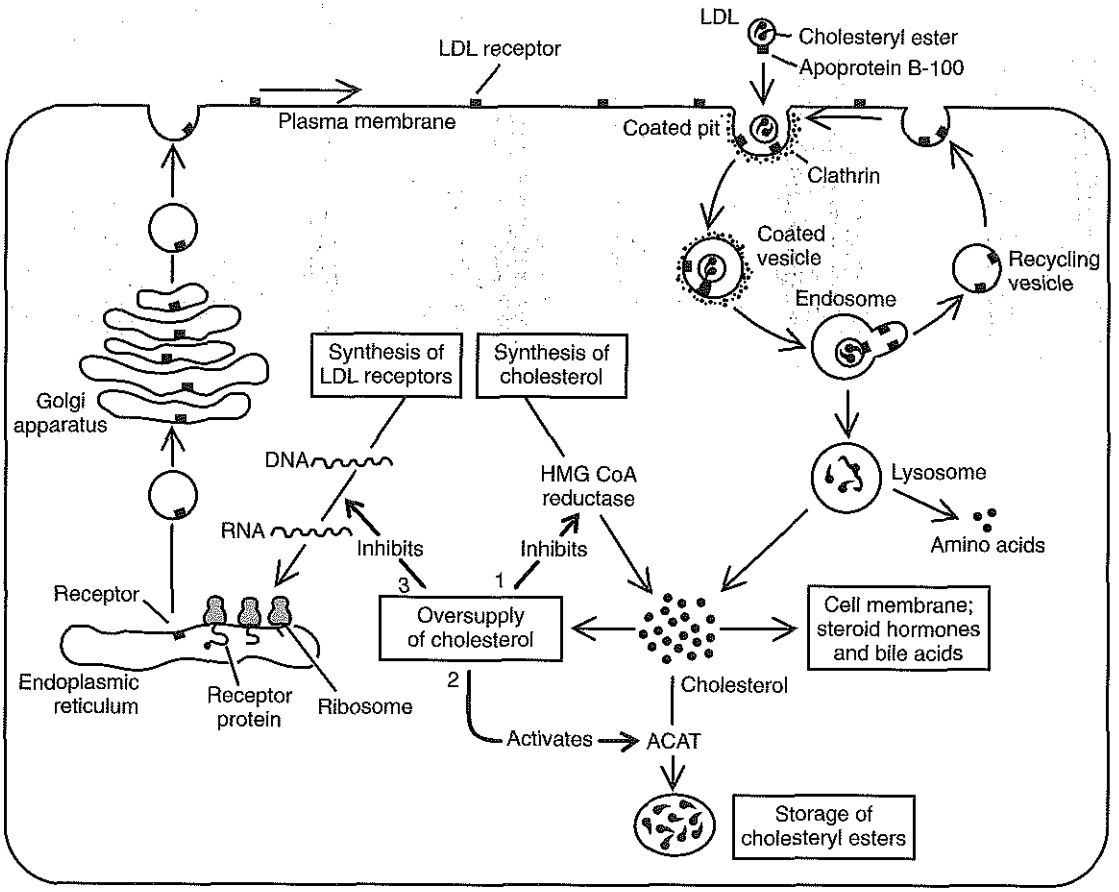

Figure 26-20 Low-density lipoprotein receptor pathway. *LDL*, Low-density lipoproteins; *ACAT*, acyl-CoA cholesterol acyltransferase; *HMG-CoA reductase*, 3-hydroxy-3-methylglutaryl coenzyme A reductase. Because of the presence of apolipoprotein B-100 on its surface, the LDL particle is recognized by a specific receptor in a coated pit and taken into the cell in a coated vesicle *(top right)*. Coated vesicles fuse together to form an endosome. The acidic environment of the endosome causes the LDL particle to dissociate from the receptors, which return to the cell surface. The LDL particles are taken to a lysosome, where apolipoprotein B-100 is broken down into amino acids and cholesterol ester is converted to free cholesterol for cellular requirements. The cellular cholesterol level is self-regulated. Oversupply of cholesterol will lead to (1) decreased rate of cholesterol synthesis by inhibiting HMG-CoA reductase, (2) increased storage of cholesteryl esters by activating ACAT, and (3) inhibition of manufacture of new LDL receptors by suppressing the transcription of the receptor gene into mRNA. *(From Brown MS, Goldstein JL. How LDL receptors influence cholesterol and atherosclerosis. Sci Am 1984;251:58-66. Copyright 1984 by Scientific American, Inc. All rights reserved.)*

Golgi apparatus, transported by exocytosis into the extracellular space, and introduced into circulation through the fenestrae of the hepatic sinusoidal endothelium in the form of nascent VLDL (see Figure 26-19). This triglyceride-rich particle (55% by mass) contains apo B-100, apo E, and small amounts of C apolipoproteins on its surface. Additional C apolipoproteins are transferred after secretion from circulating HDL. As in the case of chylomicron metabolism, apo C-II present on the surface of VLDL activates LPL on endothelial cells, which leads to the hydrolysis of VLDL triglycerides and the release of free fatty acids. It is important to note, however, that the rate of hydrolysis of VLDL triglyceride is significantly lower than that of chylomicron triglyceride. The average residence time of VLDL triglyceride is 15 to 60 minutes, compared with the 5 to 10 minutes of chylomicron triglyceride.[111] This difference may be attributed to the fact that VLDL particles are smaller and bind to fewer LPL molecules than chylomicrons.

During the hydrolysis of VLDL triglycerides, the C apolipoproteins are transferred back to HDL. VLDL particles are thus converted to VLDL remnants, some of which are taken up by the liver and the rest converted to smaller, denser particles called IDL. Large IDL particles, which also have several molecules of apo E, bind the hepatic remnant receptors and are removed from circulation. In humans, about 50% of IDL is removed by hepatocytes.

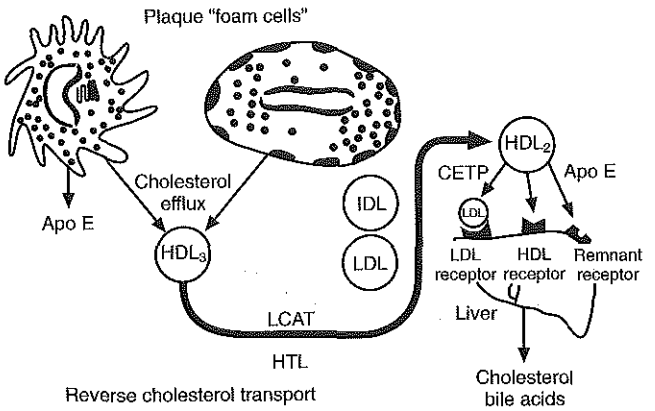

Figure 26-21 Reverse cholesterol transport pathway. *HDL*, High-density lipoproteins; *LDL*, low-density lipoproteins; *IDL*, intermediate-density lipoproteins; *HTL*, hepatic lipoprotein lipase; *LCAT*, lecithin cholesterol acyltransferase; *CETP*, cholesteryl ester transfer protein; *apo E*, apolipoprotein E. Cholesterol is removed from macrophages and other arterial wall cells by an HDL-mediated process. The LCAT esterifies the cholesterol content of HDL to prevent it from reentering the cells. Cholesterol esters are delivered to the liver by one of three pathways: (1) cholesterol esters are transferred from HDL to LDL by CETP and enter the liver through the specific LDL receptor pathway; (2) cholesterol esters are selectively taken from HDL by HDL receptors and HDL particles are returned to circulation for further transport; or (3) HDL have accumulated apo E and therefore the particles can enter the liver through remnant receptors. *(From Gwynne JT. High density lipoprotein cholesterol levels as a marker of reverse cholesterol transport. Am J Cardiol 1989;64:10G-17G. Copyright 1989, with permission from Excerpta Medica Inc.)*

Surface materials from IDL, including some phospholipids, free cholesterol, and apolipoproteins, are transferred to HDL, or form HDL de novo in the circulation. Cholesteryl esters are transferred from HDL to LDL. The net result of the coupled lipolysis and the cholesteryl esters exchange reaction is the replacement of much of the triglyceride core of the original VLDL with cholesteryl esters. IDL undergoes a further hydrolysis in which most of the remaining triglycerides are removed and all apolipoproteins except B-100 are transferred to other lipoproteins. This process ends with ultimate formation of LDL.

Low-Density Lipoprotein Receptor Pathway

The mechanism by which LDL is removed from circulation is well understood. Specific receptors present in coated pits on plasma membranes recognize and bind apo B-100 of LDL (see Figures 26-19 and 26-20). The LDL particles are internalized in coated vesicles, which then fuse to form an endosome. Because of the acidic milieu of the endosome, LDL dissociates from the receptor, which returns to the cell surface for reuse, whereas LDL migrates to the lysosome. Once the LDL is delivered to the lysosome, apo B-100 is degraded to small peptides and amino acids. Cholesterol esters are also hydrolyzed, with the cholesterol then available for the synthesis of cell membranes, steroid hormones in tissue that make them, and bile acids in hepatocytes. Cells have the ability to regulate their cholesterol content. Oversupply of free cholesterol leads to (1) decreased rate of endogenous cholesterol synthesis by inhibiting the rate-limiting enzyme HMG-CoA reductase; (2) increased formation of cholesteryl esters, which is catalyzed by ACAT; and (3) inhibition of the synthesis of new LDL receptors by suppressing the transcription of the receptor gene. The inhibition of HMG-CoA reductase and suppression of the LDL receptor may occur through the interaction of the cholesterol derivative, hydroxycholesterol, with the regulatory portions of the respective genes. Compared with VLDL and chylomicrons, LDL has a relatively long residence time in the circulation, about 3 days.[111]

LDL are also taken up by extrahepatic tissue through scavenger receptors or non–receptor-mediated pinocytosis. The non–receptor-mediated uptake becomes important as plasma LDL concentrations increase, as in familial hypercholesterolemia (FH). Nonreceptor-mediated uptake is not saturable and not regulated. Scavenger receptors are unregulated as well and recognize LDL that has been modified in various ways. They are found in macrophages and other cells. Macrophages that become engorged with cholesteryl esters are called "foam cells," and are considered the earliest components of the atherosclerotic lesion. Two thirds of LDL is normally removed by LDL receptors and the remainder by the scavenger cell system.

High-Density Lipoprotein Reverse Cholesterol Transfer Pathway

High-density lipoproteins are secreted from the liver or intestine as disk-shaped nascent particles that consist primarily of phospholipids and apo A-I. Through the extracellular addition of surface components of triglyceride-rich particles, such as phospholipids, cholesterol, and certain apolipoproteins, nascent HDL is converted to spherical particles. Free cholesterol from cell membranes is also transferred to the nascent HDL (see Figure 26-21). Cholesterol is esterified by the action of LCAT in the presence of its cofactor apo A-I. The size of the HDL particle depends strongly on the amount of accumulated cholesteryl esters and the activity of LCAT. Lysolecithin, a byproduct of this reaction (see previous discussion), is then removed from circulation after binding with albumin. HDL cholesteryl esters are delivered to the liver by one of the following mechanisms: (1) cholesteryl esters are selectively taken up from HDL, probably by the hepatic HDL receptors, and HDL particles are returned to circulation for further transport; (2) cholesteryl esters are transferred from HDL to apo B-100–containing lipoprotein, a process mediated by cholesterol ester transfer protein, then taken up by the liver through receptors for these lipoprotein; or (3) HDL apo E can be recognized by the hepatic remnant receptors.[103] These processes constitute the reverse cholesterol transport mechanism, by

which cellular and lipoprotein cholesterol is delivered back to the liver for reuse or disposal.

Although LDL are the major products resulting from the catabolism of VLDL, some conversion of HDL subfractions also occurs during this process. The surface materials from triglyceride-rich particles that have been transferred to the small circulating HDL_3 are subsequently esterified by LCAT, as described earlier, to create the larger cholesteryl ester–rich HDL_2. It has been shown that in vitro HDL_2 is converted back to HDL_3 in the presence of hepatic LPL.[225] HDL_2 contains twice as many cholesterol molecules per unit of apolipoproteins as does HDL_3.

Reference Lipid, Lipoprotein Cholesterol, and Apolipoprotein Concentrations

At birth, the typical plasma cholesterol concentration is about 66 mg/dL,* equally distributed among LDL and HDL with a very small amount in VLDL. Triglyceride concentration is only about 36 mg/dL.[260†] Cord blood apo A-I, apo B-100, and Lp(a) showed mean concentrations of about 80, 33, and 4 mg/dL, respectively.[257,258] Lipid, lipoprotein cholesterol, and apolipoprotein concentrations rise sharply during the first few months of life, with LDL becoming the major carrier of plasma cholesterol, and then remain relatively unchanged until puberty. A profile consisting of a total cholesterol of about 155 mg/dL, LDL cholesterol of 90 mg/dL, HDL cholesterol of 53 mg/dL, triglycerides of 55 mg/dL, apo B-100 of 86 mg/dL, and apo A-I about 130 mg/dL is typical for a normal prepubertal subject. After puberty, there is an increase in triglycerides, LDL cholesterol, and apo B-100 in both sexes and a decrease in HDL cholesterol and apo A-I in men. Lipid concentrations continue to increase throughout adult life, with total and LDL cholesterol and apo B-100 being higher in men than in women up to age 55.[35] Thereafter, women who are not receiving estrogen supplementation have higher total and LDL cholesterol and apo B-100 than their age-matched male counterparts.[104] In contrast to the other lipids, lipoproteins, and apolipoproteins, Lp(a) concentration increases slowly and gradually to reach Lp(a) adult values after the third year of life.[258]

Plasma lipid and lipoprotein concentrations in male and female subjects are presented in Tables 26-7 through 26-10. These reference intervals have been developed using the Lipid Research Clinics (LRC) population. Although reference intervals for apo A-I and B-100 from the Framingham Heart Study using the approved World Health Organization/International Federation of Clinical Chemistry and Laboratory Medicine (IFCC) calibrators have been published,[54,55] distributions of these two proteins that better reflect the North American population have only recently

become available from the National Health and Nutrition Examination Survey III (NHANES-III) (Tables 26-11 and 26-12).[17] Since NHANES has been designed to reflect the U.S. population, data for the distribution of these proteins in the main American ethnic groups are available (Table 26-13). The availability of such information will enable the development of cut points for clinical decision. For example, for apo B-100, cut points similar to those recommended for LDL-C can be developed; the apo B-100 values, which correspond to desirable, borderline high risk, high risk, and very high risk, are 88, 115, 132, and 152 mg/dL and apo A-I values, which correspond to low and high, are 114 and 154 mg/dL.[17] Until Lp(a) measurement is standardized, the development of appropriate reference intervals is not possible.[172]

CLINICAL SIGNIFICANCE

The clinical significance of lipids is primarily associated with coronary heart disease (CHD) and various lipoprotein disorders.

Association with Coronary Heart Disease

Increased cholesterol is a factor in the cause of atherosclerotic diseases (see also Chapter 44). As early as 1910, Windaus described cholesterol in the lesions of diseased arteries. Subsequently, many studies have confirmed that free and esterified cholesterol accumulates in the aorta, coronary arteries, and cerebral vessels, and that the rate of accumulation varies among individuals. The association between serum cholesterol and atherosclerosis in humans was first suggested in 1938, when Muller and Thanhauser each demonstrated familial aggregation of hypercholesterolemia and CHD.[196,302] Further studies showed that when the total cholesterol concentration is high, the incidence and prevalence of CHD are also high.[93]

The relationship between cholesterol and atherosclerotic coronary disease is curvilinear.[102] According to the Multiple Risk Factor Intervention Trial (MRFIT), if a risk ratio of 1.0 is arbitrarily assigned at a cholesterol value of 200 mg/dL, the risk ratio increases to 2.0 at 250 mg/dL and to 4.0 at 300 mg/dL (Figure 26-22). Pathological studies have helped to explain this curvilinear relationship. When 60% of the surface of coronary arteries is covered with plaque, one enters a critical phase in which an increased serum cholesterol concentration will markedly increase coronary disease risk. The results of the LRC-Coronary Primary Prevention Trial (CPPT) showed that the use of the 95th percentile to define hypercholesterolemia is inappropriate. Data from this and other studies suggest that risk increases as cholesterol levels increase; at concentrations of 200 to 240 mg/dL, the risk begins to accelerate at a greater magnitude. On average, each 1% reduction in cholesterol (2 to 3 mg/dL) results in a ~2% reduction in CHD incidence, a relationship of considerable clinical and public health significance.[72] In addition, the Cholesterol-Lowering Atherosclerosis Study (CLAS) demonstrated the benefit of cholesterol lowering even in people with normal or moderately increased cholesterol concentrations (185 to 240 mg/dL) and those with established disease.[26]

Many epidemiological and clinical studies have shown that both increased LDL cholesterol and decreased HDL cholesterol are associated with an increased risk of CHD.[41] Some studies have demonstrated that a reduction in LDL cholesterol is correlated with regression in the atherosclerotic lesion.[32] Various investigations also demonstrated that

the small, dense LDL subfractions correlated better with CHD risk than the large, less dense LDL subfractions.[14,39] Initially, a National Institutes of Health consensus conference on triglyceride and CHD failed to establish increased fasting triglyceride concentration as an independent risk factor.[211] However, the National Cholesterol Education Program (NCEP) and the Adult Treatment Panel III (ATPIII) reports[77,203] have given triglycerides more prominence in CHD risk prediction (see section on diagnosis of lipoprotein disorders later in this chapter). Furthermore, fat tolerance and the ability to rapidly catabolize ingested triglycerides are reported to correlate well with one of the known atherogenic risk indicators, HDL_2 cholesterol.[224] The degree of hypertriglyceridemia appearing after a meal controls the extent to which the basal HDL_2 is converted by hepatic lipase, at least in vitro, to HDL_3. It has also been postulated that chylomicron remnants and IDL, the products of the breakdown of triglyceride-rich lipoprotein, are important in atherogenesis.[337] They may promote atherosclerosis when their concentrations in plasma are high or their presence in circulation is prolonged. A scavenger cell receptor for chylomicron remnants that would provide a mechanism for entry of chylomicron cholesterol in the arterial wall has been identified.

In the early 1970s, Alaupovic suggested that apolipoproteins should also be considered when evaluating the contribution of lipids and lipoproteins to the development of atherosclerotic disease.[2] Several studies demonstrated that in people with CHD, changes in the serum concentrations of apo A-I and apo B-100 are similar to those for HDL and LDL, respectively. Apo B-100 values were increased and apo A-I values were decreased in people with CHD compared with those without disease. In most studies, apo A-I and apo B-100 were somewhat better discriminators of people with CHD than the cholesterol concentration of the corresponding lipoprotein,[145,166] at least in univariate analyses. Further-

more, these two apolipoproteins were shown to correlate better with the degree of coronary stenosis than LDL and HDL cholesterol.[200] It has also been shown that only 14.5% of patients with myocardial infarction younger than the age of 60 years have LDL cholesterol above the 95th percentile. In contrast, 35% of these patients have apo B-100 above the 95th percentile.[284] The measurement of apo B-100 provides information regarding the number of apo B-100–containing particles. If the concentration of LDL cholesterol is normal or slightly increased but apo B-100 is greatly increased, it is likely that the number of the small, more atherogenic and dense, LDL particles is high. Increased serum apo B-100 and decreased apo A-I concentrations were also found in children of parents with premature atherosclerotic disease.[83] These findings suggest that apolipoproteins may be good predictors of the possibility of future CHD. The Familial Atherosclerosis Treatment Study (FATS) demonstrated that the treatment of men, younger than 62 years of age with documented CHD, with-lipid-lowering agents on the basis of their apo B-100 concentration (>the 95th percentile, 125 mg/dL) alone is beneficial. A reduction in apo B-100 concentration in these patients caused a reversal of angiographically demonstrable coronary atherosclerosis and reduced the incidence of clinical events.[32] Data from the Air Force/Texas Coronary Atherosclerosis Prevention Study have shown apo B-100 to be the single most significant and consistent lipid measurement to predict future risk of coronary events.[98] The apo B-100/A-I ratio was a better discriminator of risk than the LDL-C/HDL-C ratio. Data from this study also suggested that the mechanism of the benefit associated with lovastatin-mediated changes in LDL-C and HDL-C may be, in part, a function of the changes in apo B-100 and apo A-I. Findings from the Quebec Cardiovascular Study also showed apo B-100 to be a more powerful independent predictor of CHD than LDL-C.[151] The association of CHD risk with Lp(a) and apo E concentra-

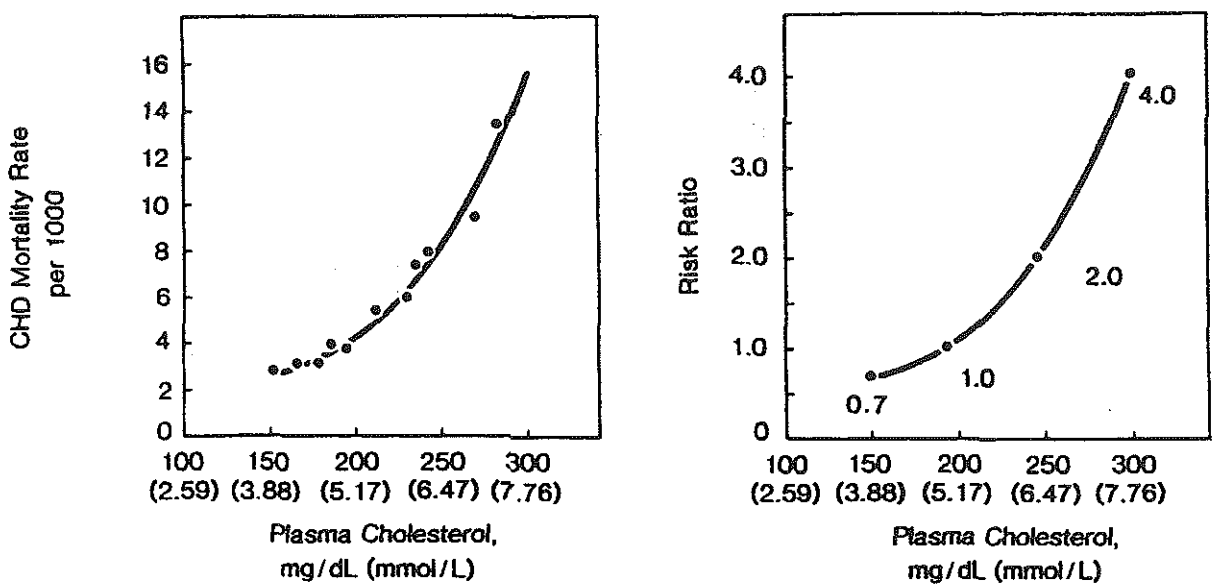

Figure 26-22 Relationship between cholesterol concentration and coronary heart disease mortality expressed by yearly rate per 1000 and risk ratios (Multiple Risk Factor Intervention Trial [MRFIT] participants). *(From Grundy SM. Cholesterol and coronary heart disease: A new era. JAMA 1986;256:2849-55. Copyright 1986, American Medical Association.)*

tions and the various apo E phenotypes is presented later in this chapter.

Although CHD is manifested clinically in the fourth decade of life, evidence clearly indicates that atherosclerosis, its major cause, is a process that begins early in life and progresses silently for decades. Autopsies performed on young American soldiers killed in action in Korea[74] and Vietnam[185] revealed atherosclerotic lesions. Coronary artery lesions were also found in aortas beginning at the age of 3 years[289] and in coronaries starting at the age of 10 years in the International Atherosclerosis Project.[294] In the Pathobiological Determinants of Atherosclerosis in Youth (PDAY) study, intimal lesions appeared in all the examined aortas and more than half of the right coronary arteries of the youngest age group (15 to 19 years) and increased in prevalence and extent with age through the oldest age group (30 to 34 years).[293] This

study also demonstrated that some regions of the arteries were lesion prone and others were lesion resistant and the propensity to develop raised or advanced lesions differed among right coronary artery, abdominal aorta, and thoracic aorta. Findings from the Bogalusa Heart Study[328] indicated a correlation between systolic blood pressure, higher total and LDL cholesterol, and lower HDL cholesterol concentrations and the degree of coronary and aortic atherosclerosis in children and adolescents.[24] In the PDAY study, postmortem cholesterol and thiocyanate concentrations predicted the extent of coronary and aortic atherosclerosis, respectively, in autopsies of those aged 14 to 34.[332] Therefore, a direct relation between determinant risk factors and the extent of atherosclerotic lesions in youth seems to exist. Furthermore, children in countries with an increased incidence of CHD were reported to have higher cholesterol concentrations than children of countries with low incidence.[139] About 5% of American children, 5 to 18 years of age, have cholesterol concentrations above 200 mg/dL. In addition, findings from the Muscatine, Bogalusa, and Princeton School District studies have demonstrated that serum cholesterol and lipoprotein cholesterol concentrations cluster in families and display a moderate degree of longitudinal tracking.[134,154,155,328] Thus in those people who have high total and lipoprotein cholesterol concentrations, the levels tend to remain high as they get older. This suggests that the identification and treatment of children who may be at high risk for development of CHD offer the possibility of preventing or delaying the development of this disease.

Disorders of Lipoprotein Metabolism

Dyslipoproteinemia is diagnosed in most patients using plasma lipid and lipoprotein cholesterol concentrations. Dyslipoproteinemias have previously been defined in terms of arbitrarily defined cut points for lipids and lipoprotein, but are now based on the relationship between lipoprotein levels and the risk for CHD (see discussion later in this chapter).

Primary Versus Secondary Hyperlipoproteinemia

On diagnosing hyperlipidemia in a given patient, the hyperlipidemic status should be evaluated to determine whether it is a primary lipoprotein disorder or secondary to any of a variety of metabolic diseases. The diagnosis of primary hyperlipidemia is made after secondary causes have been ruled out. The causes of secondary hyperlipoproteinemia are listed in Table 26-14. The most commonly seen secondary causes in the first year of life are glycogen storage disease and congenital biliary atresia. Hypothyroidism, nephrotic syndrome, and diabetes mellitus are more prevalent later in childhood. Exogenous factors, such as dietary and alcohol intake, oral contraceptives, diabetes mellitus, and pharmacological agents (e.g., steroids, isotretinoin [Accutane], and β-blockers), are the main secondary causes of hyperlipidemia in adults.[125,147]

TABLE 26-14 Causes of Secondary Hyperlipidemia and Dyslipoproteinemia

Disorder	Cause
Exogenous	Drugs: corticosteroids, isotretinoin (Accutane), thiazides, anticonvulsants, β blockers, anabolic steroids, certain oral contraceptives
	Alcohol
	Obesity
Endocrine and metabolic	Acute intermittent porphyria
	Diabetes mellitus
	Hypopituitarism
	Hypothyroidism
	Lipodystrophy
	Pregnancy
Storage disease	Cystine storage disease
	Gaucher's disease
	Glycogen storage disease
	Juvenile Tay-Sachs disease
	Niemann-Pick disease
	Tay-Sachs disease
Renal	Chronic renal failure
	Hemolytic-uremic syndrome
	Nephrotic syndrome
Hepatic	Benign recurrent intrahepatic cholestasis
	Congenital biliary atresia
Acute and transient	Burns
	Hepatitis
	Acute trauma (surgery)
	Myocardial infarction
	Bacterial and viral infections
Others	Anorexia nervosa
	Starvation
	Idiopathic hypercalcemia
	Klinefelter's syndrome
	Progeria (Hutchinson-Gilford syndrome)
	Systemic lupus erythematosus
	Werner's syndrome

Familial Dyslipoproteinemias

Historically, lipoprotein phenotypes reflecting lipoprotein metabolic disorders were classified according to Fredrickson and co-workers. However, these disorders are more rationally approached based on the four metabolic pathways discussed previously (see Figures 26-18 through 26-21). Defects in these pathways, leading to hyperlipidemia, may be related to (1) increased production of lipoproteins, (2) abnormal intravascular processing (e.g., enzymatic

hydrolysis of triglyceride), and (3) defective cellular uptake of lipoproteins. Finally, a significant decrease in production or an increase in removal of lipoproteins can lead to a marked reduction in lipid and lipoprotein concentrations.

Deficiency in Lipoprotein Lipase Activity

This disorder is characterized by marked hyperchylomicronemia and a corresponding hypertriglyceridemia (triglyceride as high as 10,000 mg/dL).[36] As discussed previously, LPL is essential for the hydrolysis of triglyceride and the conversion of chylomicrons to chylomicron remnants. The massive accumulation of chylomicrons in the circulation indicates the inability to catabolize dietary fat. The concentration of VLDL cholesterol is usually normal and the concentrations of HDL cholesterol and LDL cholesterol are low (type I pattern). Furthermore, the concentration of apo C-II, the activator of LPL, is normal.

This disorder is usually expressed in childhood. In a review of 43 cases, 35 were manifested before the age of 10.[159,160] It appears that those patients with low to absent LPL activity in all tissue present with symptoms of the disease at an early age (classic form), whereas those with deficiency in LPL activity in only one tissue become symptomatic later in life (variant forms). This disease is usually detected after recurrent episodes of severe abdominal pain and repeated attacks of pancreatitis. Eruptive xanthomas and lipemia retinalis are usually present when plasma triglyceride concentrations exceed 2000 and 4000 mg/dL, respectively.[36] The acuteness of the symptoms is directly proportional to the degree of hyperchylomicronemia. It is important to note that patients with this disorder *do not* appear to be predisposed to atherosclerotic disease.

The diagnosis is made by the determination of LPL activity in postheparin plasma. The intravenously administered heparin binds LPL, causing its dissociation from heparan sulfate, present on the surface of endothelial cells, and subsequent release to plasma.[117] This autosomal recessive disorder is extremely rare (one per million individuals). More than 40 insertions and deletions in the LPL gene that lead to absent or truncated LPL protein with defective catalytic activity have been described.[36]

Deficiency in Apolipoprotein C-II

Deficient or defective apo C-II, the required activator for LPL, reduces the activity of this enzyme, impairs chylomicron catabolism, and increases plasma triglycerides (500 to 10,000 mg/dL). Those affected by this disorder have less than 10% of the normal concentration of apo C-II, the minimum amount necessary for normal LPL activity.[122] Total cholesterol tends to vary considerably (150 to 890 mg/dL) in these patients, but HDL and LDL cholesterol concentrations are below the 5th percentile. Furthermore, plasma apo A-I, A-II, and B-100 concentrations are decreased, whereas apo C-III and E concentrations are increased.

Although the clinical symptoms are similar to those seen in patients with LPL deficiency, they are usually milder and expressed at a later age. The predominant symptom is usually recurrent abdominal pain caused by attacks of pancreatitis. Eruptive xanthomas and lipemia retinalis are not usually seen in these patients. As with LPL deficiency, patients with apo C-II deficiency are not predisposed to atherosclerosis.

The diagnosis is made by the documentation of low LPL activity in postheparin plasma in the absence of added apo C-II. Normal enzymatic activity is restored by the addition of normal apo C-II to the assay mixture. In another approach, the absence of apo C-II can be recognized using an immunoassay for apo C-II. However, the latter approach may not distinguish between normal subjects and those with normal levels of a nonfunctional form of apo C-II. The defective apo C-II disorder is inherited in an autosomal recessive mode, but at a lower frequency than LPL deficiency. More than 10 structural defects in the apo C-II gene that lead to the absence of apo C-II or the production of a defective apo C-II molecule have been described.[36] Subjects heterozygous for a defective apo C-II gene have normal lipid and lipoprotein profiles, because a sufficient amount of normal apo C-II is usually present to activate LPL.

Familial Combined Hyperlipidemia

About 10% to 15% of patients with premature CHD actually have familial combined hyperlipidemia (FCHL).[90] This disorder is recognized as a distinct phenotype by studying family members of survivors of myocardial infarction. Patients with FCHL can have increased plasma concentrations of total and LDL cholesterol (type IIa), or triglyceride (type IV), or both (type IIb). In all cases, apo B-100 concentrations are increased. The presentation of lipoprotein patterns can vary in an individual with time. Furthermore, patients with hypertriglyceridemia with normal partners tend to have offspring with hypercholesterolemia, and vice versa.[102]

FCHL appears to result from the overproduction of VLDL and apo B-100. Kinetic studies have shown that the rate of flux of apo B-100 from VLDL in FCHL is approximately twice that of normal subjects.[44,58] This causes apo B-100 to be increased (more than 125 mg/dL) even in subjects with normal LDL cholesterol. Because of the decreased lipid-to-protein ratio in these patients, both VLDL and LDL particles tend to be small and dense. When increased, LDL cholesterol is about 190 mg/dL, but is lower than that seen in heterozygous familial hypercholesterolemia. Triglyceride levels are usually between 200 and 400 mg/dL, but can be significantly higher. The concentration of HDL cholesterol is usually mildly depressed, particularly in the presence of hypertriglyceridemia. Xanthomas and other clinical symptoms of hyperlipidemia, other than atherosclerosis, are not very common in these patients. The association of FCHL with CHD incidence is high. In addition to the increased IDL in these patients, the presence of high concentrations of small, dense LDL and low concentrations of HDL cholesterol might explain their increased risk.

Although the mutation(s) responsible for FCHL remain unknown, this disorder is associated with a major gene, apparently interacting with other genes, and has a prevalence of 1 in 100 persons. Although the expression of FCHL is delayed until adolescence, young children from families with premature CHD can present with increased cholesterol or triglyceride, or both.[147]

Hyperapobetalipoproteinemia

This disorder is characterized by increased LDL-apo B-100 concentrations with normal or moderately increased concentrations of LDL cholesterol.[148,282] The ratio of LDL cholesterol to apo B-100 is therefore reduced in these patients (≤1.2).[148] Total cholesterol and triglyceride may be normal but are usually increased, and HDL cholesterol and apo A-I are decreased. This disorder appears to be caused by an overproduction of VLDL and apo B-100 in the liver, which leads to the formation of the atherogenic small and dense LDL.[148] The exact mode of inheritance and prevalence of this disorder remain unclear. However, about one third of children of a parent with premature CHD or hyperapobetalipoproteinemia will have this disorder.[283] Features common to hyperapobetalipoproteinemia have also been reported to occur in patients with FCHL, suggesting metabolic and genetic associations between the two disorders.

Familial Hypertriglyceridemia

The production of large VLDL with abnormally high triglyceride content appears to be responsible for familial hypertriglyceridemia (FHTG).[129] The actual number of VLDL particles produced by the liver, however, is not increased. The cholesterol content of VLDL is also increased, but plasma LDL cholesterol and apo B-100 concentrations are normal. This finding suggests that the conversion of VLDL to LDL is not increased in these patients. Furthermore, plasma HDL cholesterol in FHTG is often dramatically decreased, probably secondary to the hypertriglyceridemia.

The cause of the overproduction of VLDL triglyceride is unknown. The administration of estrogen and corticosteroids aggravates hypertriglyceridemia in these patients and can sometimes lead to acute pancreatitis. The diagnosis of FHTG requires study of other family members to differentiate this disorder from FCHL. This disorder appears to be inherited in an autosomal dominant pattern with a delayed expression and an estimated frequency in the population at about 1:500 persons. About one in five children born to affected parents manifest the phenotype early in life.[87]

Type V Hyperlipoproteinemia

This disorder is characterized by an increase in both chylomicrons and VLDL. Although the exact cause for this disorder is not known, it may be due to an increased production or a decreased removal of VLDL, or to a combination of both. The activity of LPL in these patients is either normal or low, and the plasma concentration of apo C-II is normal.[147]

Although this disorder is not usually expressed in childhood, several affected preadolescents have been described.[147] Clinical presentations in adult patients include eruptive xanthomas, lipemia retinalis, pancreatitis, and abnormal glucose tolerance with hyperinsulinism.[36] Premature atherosclerotic complications are not as commonly seen as with FH. This heterogeneous syndrome appears to be inherited in an autosomal dominant mode, but its genetic basis is yet to be elucidated.

Dysbetalipoproteinemia (Type III)

This disorder is caused by a primary genetic defect in the removal of remnants of both intestinal chylomicrons and hepatic VLDL.[167] As indicated earlier, apo E present on the surface of lipoprotein remnants interacts with specific hepatic receptors and facilitates the removal of these particles from the circulation. Patients with dysbetalipoproteinemia are homozygous for a mutant form of apo E (apo E_2) that cannot efficiently bind the specific hepatic receptors, leading to the accumulation of lipoprotein remnants and a cholesterol-enriched lipoprotein of density <1.006 g/mL, commonly referred to as β-VLDL or floating β-lipoprotein, in plasma. This variant form of apo E is the result of a single amino acid substitution of cysteine for the normally occurring arginine at amino acid residue 158.[329]

The disease is characterized in part by increased plasma cholesterol and triglycerides, and the concentrations of the two lipids are about the same when expressed in milligrams per deciliter. β-VLDL present in type III has been shown to contain both apo B-100 and B-48, and is therefore related to triglyceride-rich lipoprotein remnants of both hepatic and intestinal origins. Both LDL and HDL cholesterol are lower than normal in these patients.[167]

This disorder has a late onset; it rarely manifests itself in childhood.[260] The most distinctive clinical presentation of dyslipoproteinemia is the presence of palmar xanthomas, the yellow deposits that occur in the creases of the palms.[132] Tuberous and tuberoeruptive xanthomas also occur but are not unique to this syndrome. Premature atherosclerosis develops in 30% to more than 50% of these patients, particularly in the lower extremities.[295,315]

Apolipoprotein E_2 occurs in about 1% of the population in North America, and homozygotic subjects for this isoform exhibit β-VLDL. However, overt type III hyperlipoproteinemia occurs in only one to two persons per thousand in the general population (LRC prevalence study), indicating that the occurrence of the defective alleles is necessary but not sufficient to produce clinical type III hyperlipoproteinemia.[310] The development of overt hyperlipoproteinemia in these patients is modulated by genetic, hormonal, or environmental factors—such as hypothyroidism, glucose intolerance, decreased estrogen levels after menopause, obesity, and diet—that may lead to decreased LDL receptor activity, increased VLDL production, or increased plasma cholesterol

ester transfer protein. Other rare forms of mutant apo E that cause type III hyperlipoproteinemia have also been described. Because of the familial nature of this disorder and the predisposition of the patients to hyperlipoproteinemia and premature atherosclerotic disease, family members should be evaluated. The determination of the apo E phenotype or genotype may serve to better characterize family members who may be more susceptible to the development of this disorder.

Familial Hypercholesterolemia

Familial hypercholesterolemia (FH) is caused by a primary genetic defect in the LDL receptor gene. As discussed earlier, this cell surface receptor is responsible for the recognition and removal of LDL from circulation. The defects seen in patients with FH include reduced LDL binding because of defective or absent LDL receptors. In another variant of this disorder, the person may make defective LDL receptors that bind LDL normally but that cannot efficiently internalize the LDL particles.[34] FH is characterized clinically by increased plasma LDL cholesterol concentration; cholesterol deposition in skin, tendons, and arteries; and autosomal dominant transmission that is expressed in a heterozygous or homozygous mode. Heterozygous FH is one of the most commonly seen genetic metabolic disorders, with an incidence of 1 in 500 persons in the United States. The prevalence of homozygous FH is about one in a million persons. The mean plasma LDL cholesterol in children and adult heterozygotes is usually two to three times that of normal people of similar age, whereas the mean plasma LDL cholesterol of homozygotes is four to six times that of normal subjects.[89] Although the number of LDL particles is increased in these patients, their lipid composition and lipid-to-protein ratio are usually normal.[94] Apolipoprotein B-100, the main protein in LDL, is increased in proportion to LDL cholesterol. Triglyceride concentration is either normal or slightly increased, and HDL cholesterol concentration is slightly decreased in both heterozygotes and homozygotes.

Hypercholesterolemia is present at birth in most FH patients and persists throughout life. In heterozygotes, xanthomas appear toward the end of the second decade and clinical manifestations of atherosclerotic disease appear during the fourth decade.[275] In homozygotes, the unique yellow-orange cutaneous xanthomas develop by the age of 4, if they are not already present at birth.[132] Tendon xanthomas and atherosclerotic complications begin during childhood. Death from myocardial infarction invariably occurs in homozygotes before the end of the third decade.[125,147]

Although increased plasma LDL cholesterol is indicative of the heterozygous form of FH, it is not sufficient to make the diagnosis. Other more complex laboratory tests, such as the demonstration of decreased LDL receptor activity or the confirmation of a mutation in the LDL receptor gene, are necessary to confirm the presence of this disease.[89] However, in routine practice, clinical information—such as the presence of tendon xanthomas, the detection of a child with hypercholesterolemia in the patient's immediate family, and the documentation of autosomal dominant transmission—is sufficient evidence of FH. The diagnosis of homozygous FH is simpler. Patients present at a very early age with symptoms of distinct cutaneous xanthomas, juvenile atherosclerosis, and marked hypercholesterolemia (500 to 1200 mg/dL).

More than 150 different mutations in the LDL receptor gene have been shown to significantly disrupt the normal process of LDL removal from circulation.[89,114] Heterozygotes possess one normal and one mutant allele at the LDL receptor locus and therefore can remove LDL at about half the normal rate. In contrast, homozygotes or compound heterozygotes have two of the mutant alleles and hence are unable to bind or remove LDL particles.

Familial Defective Apolipoprotein B-100

This disorder results from a mutation in the apo B-100 gene rather than the LDL receptor, resulting in a single substitution of glutamine for arginine at residue 3500 of apo B-100. This substitution reduces the positive charge of apo B-100 and decreases the affinity of LDL for the LDL receptor.[286] Plasma LDL cholesterol in heterozygotes can either be normal or moderately or greatly increased because of inadequate removal of LDL particles by LDL receptors.[313] Those with increased LDL cholesterol have an incidence of CHD comparable with that in those with FH. Triglyceride and HDL cholesterol concentrations are not affected. It is very difficult to differentiate clinically between these patients and those with heterozygous FH. However, because the management of patients with the two disorders is similar, the distinction is not clinically important.[129] The frequency of this mutation is 1:500 to 1:600 hypercholesterolemic persons in populations of European descent,[305] but the mutation is very rare in non-European populations.

Familial Hypoalphalipoproteinemia

This disorder is characterized by normal plasma lipids and LDL cholesterol and reduced HDL cholesterol, below the 5th percentile.[260,270] Although patients with this disorder are clinically normal, they have a high incidence of CHD.[303] The molecular basis of familial hypoalphalipoproteinemia is unknown. This disorder is the result of either the decreased biosynthesis or the increased catabolism of HDL or apo A-I.[31] Although the mode of transmission is not certain, in some kindreds familial hypoalphalipoproteinemia is inherited as an autosomal dominant trait.

Defects in the Synthesis of Apolipoprotein A-I

In homozygous familial hypoalphalipoproteinemia, only traces of HDL cholesterol are found in plasma, and apo A-I is undetectable.[31,147] These patients have corneal clouding and are at increased risk for development of premature CHD. Heterozygotes exhibit no clinical signs but have about

half the normal concentrations of HDL cholesterol and apo A-I. Mutations—such as a rearrangement at the apolipoprotein gene locus that inactivates both apo A-I and C-III, a deletion of the entire locus, or an insertion in the apo A-I gene—lead to decreased synthesis and low concentrations of apo A-I.[130,147,215] The frequency of recessive genes associated with low HDL cholesterol levels is approximately 10% in the general population.[31]

Defects in Catabolism of Apolipoprotein A-I (Tangier Disease)

Tangier disease, so named because it was first observed in patients from Tangier Island, is characterized by (1) severely reduced plasma HDL concentration, (2) abnormal HDL composition, and (3) accumulation of cholesteryl esters in many tissues throughout the body.[12,271,274] Kinetic studies have demonstrated that increased catabolism of HDL, rather than a defect in biosynthesis, is the cause of Tangier disease.[271] Because plasma HDL concentration is very low, the detailed characterization of this lipoprotein has been difficult to accomplish. Tangier disease is caused by mutations in the *ABC1* (ATP-binding cassette) gene on chromosome 9q31 and appears to be inherited in an autosomal dominant fashion. Plasma cholesterol is decreased to about 70 mg/dL in homozygotes and to about 160 mg/dL in heterozygotes. Triglyceride concentrations vary depending on the diet.[12] In homozygotes, plasma HDL cholesterol and apo A-I concentrations are almost zero, and apo A-II is present at less than 10% of its normal concentration in apo B-100–containing lipoprotein.[13] Heterozygotes are characterized by half-normal concentrations of HDL cholesterol, apo A-I, and apo A-II.

The clinical symptoms of Tangier disease result from the deposition of cholesteryl esters in various tissue in the body. The three major clinical signs are the hyperplastic orange tonsils, splenomegaly, and peripheral neuropathy. Other clinical signs that may be seen include hepatomegaly and corneal opacities. The severely reduced HDL cholesterol and enlarged orange tonsils are pathognomonic.[12,147] Current evidence suggests that these patients have an increased incidence of CHD. Heterozygotes exhibit no clinical manifestations and can be identified only biochemically. Although the incidence of Tangier disease in children is very low, patients as young as 3 years have been identified.[147]

Diagnosis of Lipoprotein Disorders

On the basis of findings from studies such as the MRFIT and the LRC-CPPT discussed previously,[102,163,164] hypercholesterolemia in adults is now defined in terms of CHD risk. The National Institutes of Health ATP of the NCEP[203] has issued its third report for the detection, evaluation, and treatment of hypercholesterolemia (ATP III).[59] The ATP III built on earlier reports and expanded the indications for intensive cholesterol lowering. In ATP I, strategies for primary prevention of CHD in subjects with LDL-C ≥160 mg/dL or 130 to 159 mg/dL and multiple risk factors (2+) were addressed. ATP II added new features; for subjects with existing CHD, a lower LDL-C goal of ≤100 mg/dL was established and the HDL cholesterol value was given more prominence. ATP III called for intensive LDL-C lowering in several other groups of patients. In this section, only a brief description of ATP III will be presented. Those interested in more detailed information should refer to the executive summary[59] or the complete report (http://www.nhlbi.nih.gov/guidelines/cholesterol/index.htm).

TABLE 26-15 ATP III Classification of LDL, Total, and HDL Cholesterol (mg/dL)*

LDL cholesterol	<100	Optimum
	100-129	Near or above optimum
	130-159	Borderline high
	160-189	High
	≥190	Very high
Total cholesterol	<200	Desirable
	200-239	Borderline high
	≥240	High
HDL cholesterol	<40	Low
	≥60	High

Modified from executive summary of the third report of the National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III). JAMA 2001;285:2486-97.
*ATP indicates Adult Treatment Panel; *LDL*, low-density lipoprotein; *HDL*, high-density lipoprotein.

For the primary prevention of CHD, adults age 20 or older should have their fasting lipoprotein profile (total cholesterol, triglycerides, HDL-C, and LDL-C) measured once every 5 years. If a fasting sample is not available, then only total cholesterol and HDL-C should be considered. In this instance if total cholesterol is ≥200 mg/dL or HDL-C is ≤40 mg/dL, then a fasting lipoprotein profile is required. The cut points recommended for classification by ATP III are presented in Table 26-15.[63] In addition to LDL-C, other risk determinants, presented in Box 26-2, are used to assess risk and determine goals and modalities of LDL-C lowering therapy. The highest category of risk consists of those with CHD or CHD-risk equivalents (other forms of atherosclerotic disease, such as peripheral arterial disease, abdominal aortic aneurysm, and symptomatic carotid artery disease, diabetes, or multiple risk factors that confer a 10-year risk for CHD >20%, as estimated by the Framingham risk score) (Table 26-16). The Framingham risk score is calculated for a particular individual using an algorithm that includes age, gender, total cholesterol, HDL-C, history of hypertension and treatment of hypertension, and cigarette smoking. Individuals in this category carry a risk of a major coronary event of >20%/10 years. The second category of risk includes individuals with multiple risk factors (2+) in whom 10-year risk is ≤20%. The third category consists of subjects having 0 to 1 risk factors in whom 10-year risk is ≤10%.

TABLE 26-16 Categories of Risk for LDL Cholesterol Goals

Risk Category	LDL Goal (mg/dL)
CHD and CHD risk equivalents	<100
Multiple (2+) risk factors*	<130
0-1 risk factor	<160

Modified from executive summary of the third report of the National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III). *JAMA 2001;285:2486-97.*
*Refer to Box 26-2 for list of risk factors. CHD indicates coronary heart disease.

BOX 26-2 Major Risk Factors (Exclusive of LDL Cholesterol)

- Cigarette smoking
- Hypertension (blood pressure ≥140/90 mm Hg or on antihypertensive medication)
- Low HDL cholesterol (<40 mg/dL)*
- Family history of premature CHD (CHD in male first-degree relative <55 years; CHD in female first-degree relative <65 years)
- Age (men ≥45 years; women ≥55 years)

Modified from executive summary of the third report of the National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III). JAMA 2001;285:2486-97.
LDL, Low-density lipoprotein; *HDL,* high-density lipoprotein.
*HDL cholesterol ≥60 mg/dL counts as a "negative" risk factor; its presence removes one risk factor from the total count.

TABLE 26-17 Clinical Identification of the Metabolic Syndrome

Risk Factor	Defining Level
• Abdominal obesity (waist circumference)	
Men	>102 cm (>40 in)
Women	>88 cm (>35 in)
• Triglycerides	≥150 mg/dL
• High-density lipoprotein cholesterol	
Men	<40 mg/dL
Women	<50 mg/dL
• Blood pressure	≥130/≥85 mm Hg
• Fasting glucose	≥110 mg/dL

Modified from executive summary of the third report of the National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III). *JAMA 2001;285:2486-97.*
HDL, High-density lipoprotein cholesterol.

TABLE 26-18 NCEP Classification of Total and Low-Density Lipoprotein (LDL) Cholesterol in Children and Adolescents*

Category	Total Cholesterol	LDL Cholesterol
Desirable	<170	<110
Borderline	170-199	110-120
High	≥200	≥130

*All values are in mg/dL; to convert to mmol/L, multiply by 0.0259.

Although the primary target of risk-reduction therapy is LDL-C, the ATP III recognized the metabolic syndrome, a constellation of several risk factors (increased triglycerides, decreased HDL-C, obesity, hypertension, and insulin resistance), as a secondary target of therapy. By definition, those with three or more of these risk factors are considered to have the metabolic syndrome.[77] The specific criteria for the clinical identification of the metabolic syndrome are listed in Table 26-17.

The NCEP/Expert Panel on Blood Cholesterol Levels in Children and Adolescents[244] and the American Academy of Pediatrics[7,8] defined "high cholesterol" as concentrations more than the 95th percentile for total and LDL cholesterol in children and adolescents from families with hypercholesterolemia or premature vascular disease (see Table 26-18). "Borderline" total and LDL cholesterol concentrations are defined as values between the 75th and 95th percentiles. The NCEP panel referred to total and LDL cholesterol values below the 75th percentile as "desirable." Low HDL cholesterol was also defined as a concentration below 35 mg/dL. Children tend to have higher HDL cholesterol concentrations than adults. Therefore it is important to determine both LDL and HDL cholesterol concentrations before classifying the child as hypercholesterolemic. Unlike the criteria for the risk-based cholesterol classification system used in adults, the guidelines for children and adolescents were based on consensus rather than directly on the association with coronary disease, because children as a group have very little disease. When such data become available, different cutoffs may be suggested for the pediatric population.

As discussed earlier, cholesterol screening is currently recommended for all adults in the United States. However, for children such a screening program remains highly controversial. According to the NCEP[243] and the American Academy of Pediatrics,[7,8] only children over the age of 2 should be screened for hypercholesterolemia when they have a parent with hypercholesterolemia (>240 mg/dL) or a positive family history (mother, father, uncle, aunt, or grandparent) with early documented CHD (at 55 years or less), myocardial infarction, angina pectoris, peripheral vascular disease, cerebrovascular disease, or sudden cardiac death. Several studies, however, have demonstrated the weakness of

TABLE 26-19 Current Fat Intake in American Adults, Children, and Adolescents and the American Heart Association Step-One and Step-Two Diets

	Current Intake			
Nutrients	**Adults**	**Children and Adolescents**	**Step-One**	**Step-Two**
Total fat				
Percent of total calories	35%-36%	36%	<30%	<30%
Saturated fat	14%	15%	<10%	7%
Polyunsaturated fat	6%	16%	10%	10%
Monounsaturated fat	13%-14%	15%	10%-15%	10%-15%
Cholesterol (mg/day)	300-400	400-500	<300	<200

Modified from National Cholesterol Education Program, Lipid Metabolism Branch, Division of Heart, Lung, and Blood Institute: The Report of the Expert Panel on Blood Cholesterol Levels in Children and Adolescents. Bethesda, MD: National Institutes of Health, 1991.

this selective approach to screening and have advocated general screening for children.* The Bogalusa Heart Study found that by using the selective screening approach, only 50% of white children and 20% of black children with high LDL cholesterol concentration (>95th percentile) were detected. Furthermore, it has been shown that self-reported cholesterol values in the parents are an ineffective means of identifying children with high cholesterol.[245] More than 90% of children with total cholesterol greater than the 75th or 95th percentile were missed when physicians relied on cholesterol values reported by the parents. General screening, however, is expensive and time consuming and its effectiveness is limited by the fact that a significant number of children with high cholesterol concentrations will *not* remain hypercholesterolemic as adults.[155,239] Universal screening for those older than 16 has also been suggested on the basis of a finding that up to 66% of adolescents with increased LDL cholesterol are missed in a selective screening protocol.[261] When past adolescence, men usually start receiving routine health examinations about the age of 40, and although women visit their physicians earlier, it is because of gynecological needs. Those adolescents with increased LDL cholesterol who are missed in the selective screening process may not be identified until 2 decades later. At that time, the atherosclerotic process may be advanced and the dietary approach may not be sufficiently effective. Another possible yet unpopular approach is to do no screening at all. A prudent low-fat diet, such as the one outlined by the American Heart Association (AHA), can be recommended for all children (Table 26-19).[7,8] Such an approach will not create anxiety, labeling, or overzealous treatment; however, it will miss completely those children with significant hypercholesterolemia most at risk for adult CHD.

Management of Lipoprotein Disorders

Dietary and drug therapies are the cornerstones of the treatment of lipid disorders, such as hypercholesterolemia and hypertriglyceridemia.

TABLE 26-20 Nutrient Composition of the Therapeutic Life-Style Changes (TLC) Diet

Nutrient	**Recommended Intake**
Saturated fat	<7% of total calories
Polyunsaturated fat	Up to 10% of total calories
Monounsaturated fat	Up to 20% of total calories
Total fat	25%-35% of total calories
Carbohydrate	50%-60% of total calories
Fiber	20-30 g/day
Protein	Approximately 15% of total calories
Cholesterol	<200 mg/day
Total calories	Balance energy intake and expenditure to maintain desirable body weight/ prevent weight gain

Modified from executive summary of the third report of the National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III). JAMA 2001;285:2486-97.

Management of Hypercholesterolemia

According to ATP III, the clinical prevention of CHD is founded on a public health approach and entails a reduction in saturated fat and cholesterol intake (Table 26-20), increased physical activity, and weight control. Although this therapeutic life-style approach offers the opportunity for reducing the morbidity and mortality of CHD in the entire American population, more intensified preventive measures for higher-risk individuals are indicated.[77] The primary goal is to reduce one's long-term (>10 years) and short-term risk (<10 years), and the target LDL-C value depends on the person's absolute risk (Table 26-21). Certainly a more aggressive approach is recommended for those who have already suffered a coronary event or those with established

TABLE 26-21 LDL Cholesterol Goals and Cut Points for Therapeutic Life-Style Changes (TLC) and Drug Therapy in Different Risk Categories

Risk Category	LDL Goal (mg/dL)	LDL Level at Which to Initiate Therapeutic Life Style Changes (mg/dL)	LDL Level at Which to Consider Drug Therapy (mg/dL)
CHD or CHD risk equivalents (10-year risk >20%)	<100	≥100	≥130 (100-129: drug optional)
2+ Risk factors (10-year risk ≤ 20%)	<130	≥130	10-year risk 10%-20%: ≥130 10-year risk <10%: ≥160
0-1 Risk factor (10-year risk <10%)	<160	≥160	≥190 (160-189: LDL-lowering drug optional)

CHD or CHD equivalents. Specific models for therapeutic life-style changes and drug therapy in the primary prevention of CHD have been recommended by ATP III (Figures 26-23 and 26-24). As for the management of patients with metabolic syndrome, a combination approach of weight reduction, increased physical activity, and appropriate control of lipid levels is recommended.

A wide variety of pharmacological agents for cholesterol lowering in adults are available,[273] including (1) bile acid–binding resins (cholestyramine and colestipol), (2) niacin, (3) gemfibrozil, (4) probucol, and (5) HMG-CoA reductase inhibitors (e.g., atorvastatin, fluvastatin, lovastatin, pravastatin, and simvastatin) with the latter group having been found to reduce LDL cholesterol by as much as 40%. Some of these drugs are better tolerated by individual patients than others, and all but probucol have demonstrated long-term safety and ability both to increase HDL cholesterol (5% to 20% depending on the drug) and to decrease CHD risk. In certain circumstances, the drugs have been used individually or in combination. For further

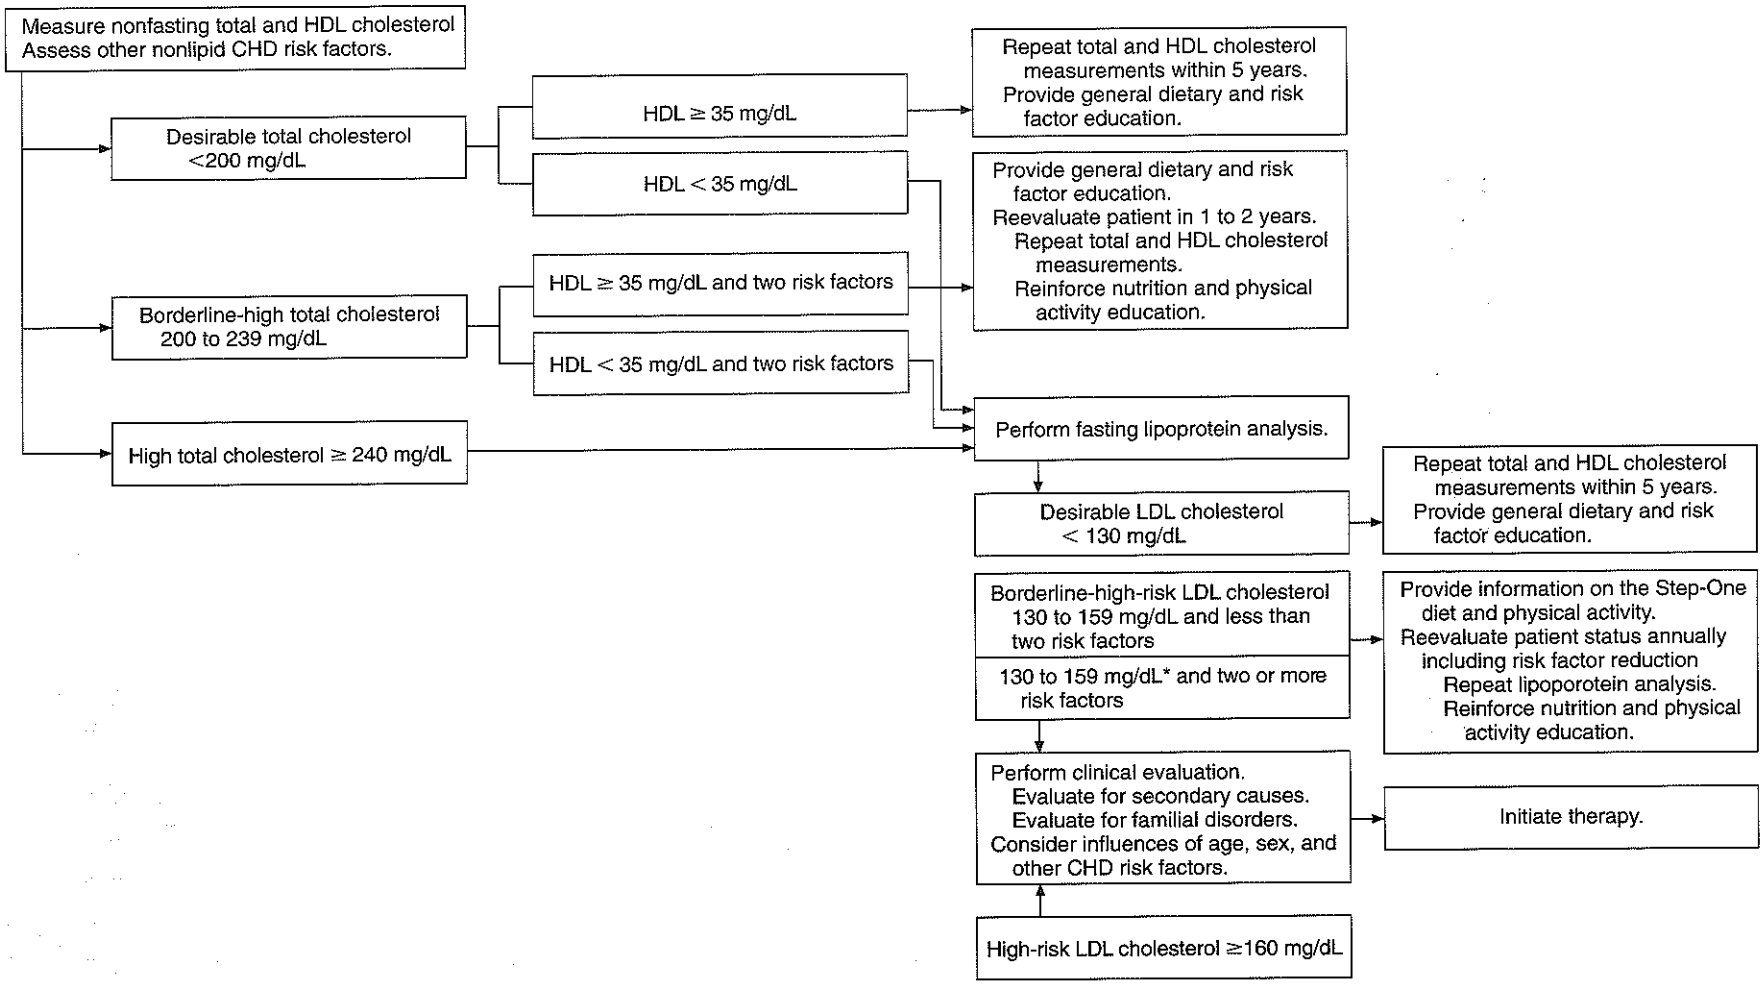
information regarding this subject, the reader is referred to reviews by Gotto.[95,96]

To lower serum cholesterol concentration in children and adolescents, the NCEP adopted a strategy that combines two complementary approaches: a population approach and an individualized approach.[244]

Population Approach

American children and adolescents have relatively high cholesterol concentrations and a high intake of saturated fatty acids and cholesterol (see Table 26-19).[244] The population approach attempts to lower the mean cholesterol concentration in the United States by instituting population-wide modifications in nutrient intake and eating habits. The AHA Step-One diet is recommended (see Table 26-19). Even a modest decrease in mean cholesterol concentration in children and adolescents, if carried into adulthood, could conceivably have a significant impact on lowering the incidence of CHD. The panel did not recommend any dietary changes for infants from birth to 2 years of age. Toddlers ages 2 and 3 should start making the transition to the recommended eating pattern. The NCEP also directed recommendations to schools, health professionals, government agencies, the food industry, and mass media to help influence and modify the eating habits of children and adolescents.



Individualized Approach

The individualized approach aims to lower cholesterol concentrations of children older than 2 years and adolescents who were identified by the selective screening process and the risk assessment protocol (Figure 26-25).[244] Those with an average LDL cholesterol concentration between 110 and 129 mg/dL should be placed on the AHA Step-One diet, counseled about other heart disease risk factors, and re-evaluated after 1 year. Those with an average LDL cholesterol concentration more than 130 mg/dL should also be placed on the AHA Step-One diet, evaluated for secondary causes, and their family members screened. If after 3 months of initiating dietary therapy, the LDL cholesterol concentration remains greater than 130 mg/dL, the patient should be placed on the AHA Step-Two diet, which entails further reduction of the saturated fatty acid and cholesterol intake (see Table 26-19). Drug therapy was recommended by the NCEP in children age 10 and older if after careful adherence to dietary therapy (6 months to 1 year) the LDL cholesterol concentration remains more than 190 mg/dL. However, the action level is lower (160 mg/dL) for patients who have a positive family history of premature CHD, or those with two or more other risk factors. Only bile acid–binding resins (cholestyramine and colestipol), which act by binding bile acids in the intestinal lumen, are recommended by the panel for use in children and adolescents. The efficacy, side effects, or safety of other cholesterol-lowering drugs have not been established in children and adolescents, and therefore their use is discouraged in this patient population.

Most FH homozygotes are resistant to drug therapy. Several alternative treatments that have been used are (1) plasmapheresis every 2 weeks, (2) partial ileal bypass or portacaval shunt to lower total and LDL cholesterol in these patients, and (3) liver transplantation, using livers from donors with functional LDL receptors. Five FH homozygote patients have already received liver transplants. Although LDL cholesterol has been normalized after surgery, this treatment has many side effects and the patients must receive immunosuppressive therapy indefinitely. A direct gene therapy in which a normal LDL gene is inserted in the patient's hepatocytes might prove to be a viable treatment option for these patients[89,125] but such an approach is not available at present.

Management of Hypertriglyceridemia

Since recent evidence-based findings have shown triglycerides to be an independent risk factor for CHD in both men and women, more emphasis on the measurement of this marker and management of those with increased triglycerides is seen in ATP III compared with earlier reports.[77]

*On the basis of the average of two determinations. If the first two LDL-cholesterol test results differ by more than 30 mg/dL, a third test result should be obtained within 1 to 8 weeks and the average value of the three tests used.

Figure 26-25 Risk assessment flowchart as recommended by the National Cholesterol Education Program Expert Panel on Blood Cholesterol Levels in Children and Adolescents. *(From The Report of the Expert Panel on Blood Cholesterol Levels in Children and Adolescents, National Cholesterol Education Program. Lipid Metabolism Branch, Division of Heart, Lung, and Blood Institute. NIH Publication No. 91-2732. U.S. Department of Health and Human Services, Public Health Service, National Institutes of Health. Bethesda MD: National Institutes of Health, 1991.)*

Furthermore the definition of a *normal* triglyceride level was changed from <200 to <150 mg/dL; values of 150 to 199 mg/dL are considered borderline high, 200 to 499 mg/dL high, and values ≥500 mg/dL very high. In the general population, several factors are associated with increased triglyceride concentrations, including obesity, cigarette smoking, physical inactivity, excess alcohol intake, and several diseases (e.g., type 2 diabetes and chronic renal failure), drugs (e.g., corticosteroids, estrogens, and retinoids), and genetic disorders (e.g., FCHL and FHTG). In clinical practice, hypertriglyceridemia is often associated with the metabolic syndrome. Triglyceride-rich lipoproteins or remnant lipoproteins are currently recognized to be atherogenic. In practice, VLDL cholesterol is used as a measure of these atherogenic lipoproteins. Therefore the ATP III suggested the addition of non-HDL cholesterol (total cholesterol-HDL cholesterol) as an indicator for all atherogenic lipoproteins (mainly LDL and VLDL).[77] The non-HDL-C is used as a secondary target of therapy in persons with triglycerides ≥200 mg/dL. The goal for non-HDL cholesterol in those with increased triglycerides is 30 mg/dL above that set for LDL cholesterol. The treatment of hypertriglyceridemia depends on the cause of the increase and severity. Those with triglycerides <200 mg/dL are treated with weight reduction and increased physical activity; for those at 200 to 499 mg/dL drug therapy is also considered (fibrate, nicotinic acid, and niacin). In the latter group, the non-HDL-C goal becomes a secondary target of therapy (Table 26-22). Those with triglycerides >500 mg/dL are usually at increased risk of pancreatitis and treated with low-fat diets (≤15% of calorie intake), weight reduction, increased physical activity, and triglyceride-lowering drugs.

TABLE 26-22 Comparison of LDL Cholesterol and Non-HDL Cholesterol Goals for Three Risk Categories

Risk Category	LDL Goal (mg/dL)	Non-HDL Goal (mg/dL)
CHD and CHD risk equivalent (10-year risk for CHD >20%	<100	<130
Multiple (2+) risk factors and 10-year risk ≤ 20%	<130	<160
0-1 Risk factor	<160	<190

Modified from executive summary of the third report of the National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III). JAMA 2001;285:2486-97.
LDL, Low-density lipoprotein; *HDL*, high-density lipoprotein; *CHD*, coronary heart disease.

Although nicotinic acid and niacin are usually the drugs of choice, a combination therapy such as gemfibrozil and resins or gemfibrozil and an HMG-CoA reductase inhibitor can also be used.[273]

MEASUREMENT OF LIPIDS, LIPOPROTEINS, AND APOLIPOPROTEINS

The lipoproteins and their lipid and apolipoprotein constituents have become increasingly important in characterizing the risk of cardiovascular diseases and in the diagnosis and management of disorders of lipoprotein metabolism. In recent decades, our knowledge of such disorders has evolved from an essentially descriptive association between elevated plasma lipids and increased risk for premature cardiovascular disease morbidity and mortality to a much broader understanding of the underlying biochemistry, physiology, and genetic interactions. An area of remarkable advance has been in understanding the contribution of the lipoproteins in the development and progression of arterial lesions. Advances have also been made in the analytical techniques and methods for measuring lipids, lipoproteins, and apolipoproteins. In this section, we begin with a brief historical perspective on the development of the measurement technology followed by more detailed discussion of the pertinent methods.

Historical Perspective and Background

The causal relationship between increased plasma concentrations of LDL and the risk of CHD and the efficacy of LDL lowering to reduce risk was widely acknowledged by the mid-1980s*; Awareness of the importance of intervention emphasized the necessity for uniform means of defining hyperlipidemia and CHD risk. Previous practice had been to use arbitrarily defined cutoffs based on prevailing lipid and lipoprotein concentrations, either in the general population or in local populations of "normal patients." Because of the relative nonspecificity of the early chemical methods for cholesterol measurement, and the different kinds of methods then in use, significant biases existed between values obtained in different laboratories, and it was not uncommon for "normal" reference intervals to be laboratory specific. Quantitation of the relationships between total or LDL cholesterol concentration and risk for CHD, the demonstration of the efficacy of treatment, and the development of reference methods and Centers for Disease Control and Prevention (CDC) standardization programs for lipids and lipoproteins,[198] however, made possible the use of risk-related cut-off points (see Tables 26-15 and 26-18). This led to the necessity for uniform definitions of hyperlipidemia based on commonly accepted risk-based lipid and lipoprotein cutoffs and the availability of accurate lipid and lipoprotein measurements.

Formation of Expert Panels

To address the issues discussed previously in this chapter, the NCEP convened expert panels to consider various aspects of diagnosis and treatment of hypercholesterolemia[77,203,244] and develop guidelines for reliable lipid and lipoprotein measurements.[237,238] Two separate laboratory panels considered issues related to blood lipid and lipoprotein measurement. The first, the NCEP Laboratory Standardization Panel, was concerned with the measurement of total cholesterol,[237] and the second, the NCEP Working Group on Lipoprotein Measurement, addressed the measurement of triglycerides, HDL cholesterol, and LDL cholesterol.[238] The recommendations of both panels include extensive reviews of lipid and lipoprotein methodology, and the interested reader is referred to the original reports for details.[237,238] Here we summarize the principal considerations and recommendations for clinical lipid and lipoprotein measurements.

Basic Issues

In developing recommendations for lipid and lipoprotein measurement, the NCEP panels considered several basic issues.

First, in most of the large-scale clinical and epidemiological studies that established the (1) relationships between lipids, lipoproteins, (2) risk for CHD, and (3) efficacy of cholesterol lowering, the measurements were made in standardized laboratories in which the accuracy of the measurements was traceable to CDC reference methods. This included studies such as the National Diet Heart Study in the 1960s, the various LRC program studies (early 1970s to 1990), Specialized Centers of Research in Atherosclerosis (early 1970s to present), and several NHANES studies conducted between 1960 and 1994.[198]

Second, the various methods used in laboratory or nonlaboratory settings should be capable of similar accuracy (i.e., the reliability of the measurements should be independent of how, where, or by whom they are made). Ideally, it should be possible to consider all lipid measurements made in the United States (and eventually globally) as if they had been made in a single laboratory. This premise does *not* require that all laboratories use the same methods; it requires only that all methods be capable of giving values equivalent to those on which the relationships between lipids, lipoproteins, and the risk for CHD were established.

Third, as new methods are developed, particularly those that may be more accurate and precise for the various lipoproteins or lipoprotein subfractions, the particular lipoprotein included in the measurement should be specified. This is to ensure that new methods could be linked to those that were used to establish the known lipoprotein-CHD risk relationships.

To achieve these aims, development of reference methods was required as accuracy targets for lipid and lipoprotein measurements and guidelines were established for analytical performance.

Analytical Challenges

Plasma lipoproteins, as macromolecular complexes that vary considerably in size, composition, and function, present considerable analytical challenge (see Table 26-4). For clinical purposes, lipoprotein concentrations have been traditionally expressed in terms of their cholesterol content, because they carry virtually all of the cholesterol that circulates in the plasma. This simplifies the methods used to measure lipoproteins because the lipoprotein fractions of interest have only to be separated from each other; the other plasma proteins do not have to be removed.

Analytically, cholesterol can be accurately and precisely measured with appropriate chemical or biochemical methods. Triglycerides, and the lipoprotein themselves, however, are not unique chemical entities. Triglycerides consist of three of many possible fatty acyl groups covalently attached to a glycerol backbone through ester linkages (see Figure 26-13).

Fatty acyl groups vary in chain length and degree of saturation, leading to a mixture of triglycerides of somewhat different molecular weights. Consequently, triglyceride methods usually measure the glycerol backbone, and triglyceride concentration is then stated only in terms of molar concentration. In the United States, however, lipids have been traditionally expressed in terms of mass concentration (milligrams per deciliter), which is an approximation requiring an assumption about the average molecular weights of the triglyceride mixture. Because palmitate, stearate, and oleate are the major fatty acids in plasma triglycerides and have similar molecular weights, the conversion between molar and mass concentration usually assumes an average triglyceride molecular weight of 885 Da, the molecular weight of tri-oleyl glycerol (olein).

The situation is even more complicated for LDL and HDL. For example, LDL consists of a population of particles varying in size and lipid composition, each containing apo B-100 as essentially the only apolipoprotein component. Thus LDL has neither a unique molecular weight nor consistent cholesterol composition. Similarly, HDL consists of two major subclasses, HDL_2 and HDL_3, differing in both their lipid and apolipoprotein compositions, and each subclass can be further separated into a number of individual subpopulations.[255] Because of these characteristics, the exact concentration and composition of a fraction identified as LDL or HDL vary depending on how the fraction is isolated. Once isolated, however, the cholesterol content can be measured accurately. A major consideration, therefore, was to define the lipoproteins in a uniform way to afford a common basis for standardization and the assessment of accuracy without inhibiting the development of new methods or necessitating the use of the same methods in all laboratories.

Analytical Approach

For more than 20 years, the CDC had maintained reference methods for cholesterol, triglycerides, and HDL cholesterol

and had operated standardization programs[198] targeted for the research laboratories. In addition, these reference methods have been used to establish the accuracy of lipid and lipoprotein measurements in a number of population studies, including the LRC prevalence and CPPT studies,[163,164] several NHANES studies conducted by the National Center for Health Statistics since the 1960s,[124] and others. From these studies, cut points for the risk characterization in patients were derived. Consequently, and because the standardization programs were already accepted as authoritative by the general laboratory and research communities, the NCEP laboratory panels recommended the CDC reference methods as the basis for defining "accuracy" in the context of recommendations for reliable lipid and lipoprotein measurements.

Using this approach had several advantages. First, it established the same basis for accuracy that had been used in developing the relationships between lipid and lipoprotein concentration and CHD, and second, it provided a reference point by which the accuracy of existing or newly developed methods could be assessed.

Lipids and Lipoproteins

Various technologies have been used to measure plasma lipids and lipoproteins and lipoprotein subfractions, including enzymatic, immunochemical, and chemical precipitation reagents, and physical methods, such as ultracentrifugation, electrophoresis, column chromatography, and others. Such methods have been reviewed extensively.[18,256] As mentioned earlier, however, the cholesterol content of any particular lipoprotein class can vary somewhat from individual to individual. Moreover, although different methods of lipoprotein separation may produce similar lipoprotein fractions, they usually do not produce identical fractions, giving rise to systematic biases between methods that purport to measure the same component. The present discussion focuses primarily on methods and procedures commonly used in clinical practice for lipid and lipoprotein measurements.

Reference Methods

Reference methods are the "gold standards" or accuracy targets that have been developed for the more common analytes, such as cholesterol, triglycerides, LDL, and HDL cholesterol.[197] The reference method for cholesterol is fully validated and credentialed through the National Reference System for the Clinical Laboratory. The other methods, although not formally credentialed, have been accepted by consensus.

Cholesterol

The CDC reference method for cholesterol[56,64,72] is based on a chemical method devised by Abell et al. In the CDC version of this method,[72] a 0.5-mL aliquot of serum is treated with 5.0 mL of alcoholic KOH (0.36 mol/L) to hydrolyze the cholesteryl esters. Total cholesterol is then extracted from the mixture with 10 mL of hexane for 15 minutes. An aliquot of the extract is dried in vacuo, and the dry residue is treated with 3.2 mL of a mixture of acetic acid, acetic anhydride, and sulfuric acid (Liebermann-Burchard reagent) for color development. After 30 minutes, absorbance is read at 620 nm using pure cholesterol as the calibrator. This method is operated according to a strict protocol requiring replicate measurements in multiple analytical runs. The method exhibits an approximate 1.6% positive bias compared with isotope dilution mass spectrometry, which, considered to be the definitive method for cholesterol, was developed and applied by the National Institute of Standards and Technology.[72] Cholesterol is expressed either in terms of molar (millimoles per liter) or mass (milligrams per deciliter) concentration. Molar concentration is converted to mass concentration using the following equation:

$$\text{mg/dL} = \text{mmol/L} \times 38.7 \quad (1)$$

The reference method, demonstrated to be readily transferable to other laboratories,[56] has been widely adopted by other reference laboratories and diagnostic manufacturers as the accuracy target and the basis for calibration in cholesterol measurements.

Triglycerides

In the CDC reference method for triglycerides,[197,198,238] the triglycerides are first extracted quantitatively with chloroform to remove water-soluble interfering substances, such as glucose and glycerol, from the serum. The extract is treated with silicic acid to remove phospholipids, and the triglycerides in the extract are subjected to alkaline hydrolysis to produce unesterified fatty acids and glycerol. The glycerol produced is oxidized to produce formaldehyde, which is then reacted with chromotropic acid for color development. The absorbance of the chromogen in the reaction mixture is measured at 570 nm.

$$\text{Triglycerides} + \text{KOH} \rightarrow \text{fatty acids} + \text{glycerol} \quad (2)$$

$$\text{Glycerol} + \text{periodate} \rightarrow \text{formic acid} + \text{formaldehyde} \quad (3)$$

$$\text{Formaldehyde} + \text{chromotropic acid} \rightarrow \text{chromogen} \quad (4)$$

The results are expressed either in terms of molar concentration (millimoles per liter) or mass concentration (milligrams per deciliter). The following equation is used to convert mmol/dL to mg/dL:

$$\text{mg/dL} = \text{mmol/L} \times 88.5 \quad (5)$$

The equation assumes an average molecular weight of 885 g/mole (triolein) for plasma triglycerides. In addition, because of the preliminary extraction and adsorption steps, the CDC reference method measures only the glycerides, and does *not* include free glycerol, the so-called triglyceride blank.

Because this assay is so complex, sensitive, and tedious, it has not been readily transferred to other laboratories. As an expedient to facilitate standardization of triglyceride

measurements, a designated comparison method (DCM) has been developed by the Cholesterol Reference Method Laboratory Network, involving similar extraction steps followed by more robust enzymatic quantitation of the triglyceride-derived glycerol.[81] This DCM, established in other reference laboratories, is expected to become the secondary accuracy target for triglycerides.

High-Density Lipoprotein Cholesterol

Both a reference method and a designated comparison method have been developed to measure HDL cholesterol.

Reference Method. Because HDL consists of several populations of particles that vary somewhat in their cholesterol content, HDL is commonly defined in terms of the method used to prepare the HDL-containing fraction. The CDC reference method[104,197] uses a combination of ultracentrifugation and polyanion precipitation to prepare the HDL-containing fraction. The cholesterol in this fraction is then quantitated using the CDC reference method for cholesterol. The method is as follows: VLDL and chylomicrons, if present, are first removed by ultracentrifugation of an accurately measured volume of serum for 18 hours at 105,000 × *g*. Under these conditions, VLDL and any chylomicrons accumulate as a floating layer at the top of the ultracentrifuge tube (d = 1.006 g/mL). A tube-slicing technique is used to remove the VLDL fraction.[104,197] The infranatant, which contains IDL, LDL, Lp(a), HDL, and the other serum proteins, is recovered quantitatively. The apo B-100–containing lipoproteins in this fraction are then precipitated with heparin sulfate (1.3 mg/mL) and $MnCl_2$ (0.046 mol/L). The precipitate is removed by centrifugation,[104,197] and cholesterol in the clear supernatant is measured. HDL cholesterol is expressed either in molar or mass concentration; molar concentration is converted to mass concentration using equation (1).

Heparin-$MnCl_2$ was selected as the precipitation reagent primarily for historical reasons because it was the method most commonly used in early studies to establish the relationship between HDL cholesterol concentration and the risk for CHD. The ultracentrifugation step was included to prevent interference with sedimentation of the apo B-100–containing lipoproteins by the lighter triglyceride-rich lipoproteins, VLDL, and chylomicrons.

Designated Comparison Method. Only a few laboratories have an ultracentrifuge and the experience required to reliably perform the CDC reference method for HDL cholesterol. Furthermore, ultracentrifugation is expensive and necessitates obtaining an impractically large specimen volume, typically 5.0 mL. As an practical alternative, the Cholesterol Reference Method Laboratory Network (CRMLN) laboratories developed and validated a modified dextran sulfate (50,000 Da) procedure as a DCM to provide results approximately equivalent to those of the CDC RM but avoiding ultracentrifugation.[135] The $MgCl_2$ concentration in the precipitant reagent was decreased slightly from that used in the previously published primary method to increase the HDL cholesterol values slightly, achieving closer agreement with the CDC reference method.

Low-Density Lipoprotein Cholesterol

The CDC has also defined a reference method for LDL cholesterol based on the same techniques described above for HDL cholesterol.[197] After ultracentrifugation to remove the VLDL and any chylomicrons present, the bottom fraction (d > 1.006) is subjected to precipitation by heparin and manganese as described previously. After measurement of cholesterol in the d > 1.006 fraction and in the heparin-Mn^{2+} supernatant solution, LDL cholesterol is calculated by difference. It should be noted that the LDL fraction as measured by this reference method is a so-called "broad-cut" fraction including any IDL and Lp(a).

Application of the Reference Methods to Standardization

Background

Early efforts in the mid1980s to achieve general standardization of methods used by clinical laboratories began with a fairly traditional approach with secondary reference materials provided to the laboratory community. The reference materials consisted of lyophilized serum pools with target values assigned based on replicate measurements using the reference methods. However, problems were recognized with this approach, primarily from the confounding effects of matrix changes in the reference materials.[191] In practice, conventional reference materials prepared from pooled serum, often deteriorated, sometimes spiked with artificial analytes, and subjected to freezing and freeze drying, did not assay like fresh patient specimens with most routine methods. In several notable cases diagnostic manufacturers used the secondary reference materials to assign presumably reliable targets to their calibrators, but subsequently found that results on patient specimens became quite inaccurate. The problem was compounded by national proficiency testing programs, which in an attempt to improve accuracy began reporting reference method target values with similarly prepared survey materials. Laboratories were adjusting calibration to achieve apparent accuracy on the survey materials; however, in some instances results on actual patient specimens were made inaccurate.

Recognition of these problems focused attention on the issues of "analyte" and "matrix" effects in reference materials.[191] Common procedures used in preparing secondary reference materials were inducing changes in the analytes themselves and in the other constituents and fluids surrounding the analytes that made their analyses no longer comparable with measurements in authentic fresh patient specimens. After considerable study and deliberation, the conclusion was reached that the only universally reliable means of transferring accuracy from the reference methods to diagnostic manufacturers and individual laboratories was through direct comparison studies on fresh, representative patient specimens.[327] As a consequence, the CDC and other groups cooperated to organize a network of reference labo-

ratories providing the reference methods and fresh sample comparison studies.

The Cholesterol Reference Method Laboratory Network

Because the CDC standardization laboratory maintaining the reference methods did not have the capacity to perform all of the necessary comparison studies directly, it was obvious that the reference laboratory capability would have to be expanded to accommodate the needs of the industry and laboratory community. To this end, the CDC and a number of other interested laboratories cooperated to establish the CRMLN. Each participating network laboratory underwent stringent protocols to transfer the CDC reference methods and to maintain comparability with the CDC. In turn the network laboratories performed comparison studies using fresh patient sera with the diagnostic manufacturers and with individual laboratories. Throughout the 1990s the network was large and quite active to accommodate the demands of comparison studies. As standardization has steadily improved in subsequent years, the level of activity has declined and the number of domestic U.S. network laboratories has decreased. However, at the same time the network laboratory program has expanded to include more international laboratories.

In 2004 the CRMLN included four experienced U.S. laboratories and seven international partner laboratories in Canada, Europe, Asia, and South America (Boxes 26-3 and 26-4). The network offers protocols, based on National Committee on Clinical Laboratory Standards guidelines,[209] whereby diagnostic manufacturers ensure accuracy by completing comparison studies with the reference method.[199] A system qualifies for certification by demonstrating agreement within specified limits for total, HDL, and LDL cholesterol and for triglycerides. Based on comparison results, calibrator set points are adjusted if necessary to bring performance into agreement with the reference methods. Diagnostic manufacturers and distributors and instrument partners are encouraged to certify their systems at least every 2 years and to ensure that every production lot is calibrated to maintain accuracy consistent with the accuracy targets, which can be accomplished by ongoing participation in the CDC and/or CRMLN program. The CDC website (http://www.cdc.gov/nceh/dls/crmln/crmln.htm) provides details of the program, protocols for comparison studies, contact information for the CDC and/or CRMLN, and a listing of the commercial methods that have qualified for certification.

Clinical laboratories can promote standardization by encouraging their kit suppliers to participate in the CRMLN comparison process. In addition, individual laboratories can also make arrangements with a CRMLN laboratory to participate in an abbreviated certification protocol for total cholesterol and complete comparison studies for the other analytes, especially useful in the case of new or modified systems. The CRMLN program is supported by modest user fees.

Routine Methods

Reference methods are complex, time consuming, at least partially manual, and require a high level of expertise for reliable operation. Consequently, simpler and more practical methods have evolved for routine clinical use.

Cholesterol

Enzymatic methods for cholesterol measurement are precise, accurate when calibrated appropriately, and easily adapted for use on modern analyzers. Commercially available cholesterol reagents commonly combine all of the enzymes and other required components into a single photometric reagent. The reagent usually is mixed with a 3- to 10-μL aliquot of serum or plasma, incubated under controlled

conditions for color development, and absorbance measured in the visible portion of the spectrum, generally at about 500 nm. The reagents typically use a bacterial cholesteryl ester hydrolase to cleave cholesteryl esters.

$$\text{Cholesteryl ester} + H_2O \xrightarrow{\text{Cholesteryl ester hydrolase}} \text{cholesterol} + \text{fatty acid} \quad (6)$$

The 3-OH group of cholesterol is then oxidized to a ketone in an oxygen-requiring reaction catalyzed by cholesterol oxidase,

$$\text{Cholesterol} + O_2 \xrightarrow{\text{Cholesterol oxidase}} \text{cholest-4-en-3-one} + H_2O_2 \quad (7)$$

H_2O_2, one of the reaction products, is measured in a peroxidase catalyzed reaction that forms a colored dye.

$$H_2O_2 + \text{phenol} + \text{4-aminoantipyrine} \xrightarrow{\text{Peroxidase}} \text{quinoneimine dye} + 2\,H_2O \quad (8)$$

These methods are subject to interference from other colored compounds or those that compete with the oxidation reaction, such as bilirubin, ascorbic acid, and hemoglobin. Assays are usually linear up to about 600 or 700 mg/dL. Reagents have been refined by adding substances such as bilirubin oxidase and dual wavelength readings to minimize the effects of hemolysis, and interference from bilirubin is generally not an issue now in concentrations below 5 mg/dL.[18,64,201] Enzymatic reagents are not entirely specific for cholesterol, because β-hydroxy sterols and plant sterols (e.g., β-sitosterol) can also react. In human serum or plasma, however, this is not a major problem because these interfering sterols are generally at very low concentrations.

In practice, reagent formulations vary from manufacturer to manufacturer. In most cases, the reagent from a particular manufacturer will have been optimized for use with one or several specific instruments and calibration materials, usually those sold by that manufacturer. In the past few years, most manufacturers have been supplying calibration

materials with assigned values that are traceable to the CDC reference method, which has helped reduce interlaboratory variation. Thus cholesterol methods are best thought of as "measurement systems" composed of reagent, calibrator (cholesterol standard), and instrument. When a reagent-calibrator-instrument system from a single manufacturer is used, cholesterol measurements within a laboratory usually are accurate within 1% to 3% of reference values, and such systems are routinely operated with coefficients of variation of 1.5% to 2.5%. In some cases, however, a reagent from one manufacturer might be used with an instrument from another. In this instance, the responsibility is on the user rather than the manufacturer to ensure that reagent and sample volumes, time and temperature of incubation, and the calibration produce precise and accurate measurements. Although the cholesterol oxidase reagent described previously in this chapter is by far the most common, reagents have been developed using a cholesterol dehydrogenase sequence, which may have advantages in some instances.[131] In addition, highly sensitive enzymatic methods have been described for specialized applications.[137] Free or unesterified cholesterol can be readily quantified by deleting the cholesterol esterase from the reagent.

Triglycerides

Triglycerides also are now commonly measured with enzyme reagents directly in plasma or serum. Reagents combining all the required enzymes, cofactors, and buffers are available from various manufacturers, and as for cholesterol, such reagents are optimized for use with particular instrument-calibrator systems. Several different enzyme sequences have been used. In all of the methods, the first step is the lipase-catalyzed hydrolysis of triglycerides to glycerol and fatty acids.

$$\text{Triglyceride} + 3\,H_2O \xrightarrow{\text{Lipase}} \text{glycerol} + 3\ \text{fatty acids} \quad (9)$$

Glycerol is then phosphorylated in an ATP-requiring reaction catalyzed by glycerokinase.

$$\text{Glycerol} + \text{ATP} \xrightarrow{\text{Glycerokinase}} \text{glycerophosphate} + \text{adenosine diphosphate (ADP)} \quad (10)$$

In the most commonly used methods, glycerophosphate is oxidized to dihydroxyacetone and H_2O_2 in a glycerophosphate oxidase-catalyzed reaction,

$$\text{Glycerophosphate} + O_2 \xrightarrow{\text{Glycerophosphate oxidase}} \text{dihydroxyacetone} + H_2O_2 \quad (11)$$

and the H_2O_2 formed in the reaction is measured as described in reaction (8).

Alternatively, glycerophosphate is measured in a reduced form of nicotinamide-adenine dinucleotide (NADH)-producing reaction and the NADH measured by a spectrophotometer set at 340 nm or in a diaphorase-catalyzed reaction to form a reaction product whose absorbance is measured at 500 nm.

$$\text{Glycerophosphate} + \text{nicotinamide-adenine dinucleotide (NAD)} \xrightarrow{\text{Glycerophosphate dehydrogenase}} \text{dihydroxyacetone phosphate} + \text{NADH} + H^+ \quad (12)$$

$$\text{NADH} + \text{tetrazolium dye} \xrightarrow{\text{Diaphorase}} \text{formazan} + NAD^+ \quad (13)$$

Other methods measure the ADP produced in reaction (10), as shown in equations (14) and (15):

$$\text{ADP} + \text{phosphoenol pyruvate} \xrightarrow{\text{Pyruvate kinase}} \text{ATP} + \text{pyruvate} \quad (14)$$

$$\text{Pyruvate} + \text{NADH} + H^+ \xrightarrow{\text{Lactate dehydrogenase}} \text{lactate} + NAD^+ \quad (15)$$

The loss of NADH is measured by a photometer at 340 nm.

Enzymatic triglyceride methods are fairly specific in that they do not detect glucose or phospholipids. They are linear in the concentration range up to about 700 mg/dL, and when automated are operated with coefficients of variation in the range of approximately 2% to 3%. The methods are usually calibrated with reference solutions of pure glycerol or with serum-based secondary calibrators. However, because all of these methods measure the glycerol component, any free glycerol in the sample contributes to the apparent amount of triglyceride. Thus assessment of bias in triglyceride measurements is not as straightforward as for cholesterol because the CDC reference method includes only the triglyceride-derived glycerol. With routine methods, the decision must be made whether to correct for free glycerol by using a method that corrects for the free glycerol blank.

Triglyceride Blanks (Correction for Endogenous Glycerol). Glycerol concentrations in freshly collected serum or plasma are usually in the range of about 1 mg/dL, contributing about 5 to 10 mg/dL to the apparent triglyceride concentration. Because this small amount is medically insignificant, the triglyceride blank is usually ignored. However, blanks can be higher in samples with increased triglyceride concentrations and from patients with conditions such as diabetes or those receiving total parenteral nutrition, but even those conditions would generally not substantially affect the interpretation. However, blanks can be increased by fiftyfold to 100-fold in the rare disorder hyperglycerolemia, which results from a deficiency of glycerokinase.[182] In this case, apparent triglyceride concentrations is extremely and artifactually high unless a triglyceride blank is analyzed.

Although triglyceride blanks can in most cases be ignored in clinical measurements, they can dramatically affect conclusions about method accuracy, important in calibration or in standardization of triglyceride measurements.[52] For example, participation in the CDC standardization program requires use of a blanking method, several of which

are commercially available. Triglyceride blanking usually requires a separate analysis of glycerol, expressed in terms of equivalent triglyceride concentration, and the measured blank value is subtracted from the total triglyceride measurement.[321] Free glycerol is measured enzymatically using reactions such as shown in equations (10) and (11), using a reagent that is identical to the triglyceride reagent but lacking lipase, an approach designated two-cuvette blanking. Such a reagent has been available from the Bayer Corporation (Tarrytown, N.Y.). In an alternative two-step approach in a single cuvette, any free glycerol in the sample is consumed to produce a colorless product in a preliminary reaction before a lipase enzyme is added to cleave and measure the triglyceride-derived glycerol. Such a reagent is available from Roche Diagnostics (Indianapolis), but can be used only with analyzers capable of adding reagents sequentially.

Triglyceride blanking by either of these approaches can add considerably to the time and cost of triglyceride analysis. Another more practical alternative for routine practice, designated calibration blanking and used by some manufacturers, involves adjusting calibrator set points to compensate for the average amount of free glycerol in specimens. This is accomplished through a comparison study on actual patient specimens versus the reference method or an accurate equivalent. The calibration blanking approach will underestimate the blank in a few specimens but will give a better and reasonably reliable estimation for most specimens.

An ad hoc panel convened to consider the necessity for glycerol blanking in routine practice recommended blank corrections for specimens from inpatients but not outpatients because of the increased likelihood of free glycerol increases in the former.[52] In practice, however, blanking is usually practiced only by research laboratories and those supporting lipid clinics, particularly to facilitate participation in the CDC standardization program.

Phospholipids

Quantitative measurement of phospholipids is rare in routine clinical practice but more common in research (e.g., in studies of dietary influences). The choline-containing *phospholipids lecithin, lysolecithin, and sphingomyelin*, which account for at least 95% of total phospholipids in serum, are readily measured by an enzymatic reaction sequence using phospholipase D, choline-oxidase, and horseradish peroxidase.[183,299] Kit methods with this enzymatic sequence are available commercially. Before the availability of enzymatic reagents, the common quantitative method involved extraction and acid digestion with analysis of the total lipid-bound phosphorus.[22]

High-Density Lipoprotein Cholesterol

Under current recommendations for characterizing the cardiovascular disease risk in patients, measurement of the two *major cholesterol-carrying lipoproteins*, HDL and LDL, are most important. Characterization of the beta-VLDL characteristic of the uncommon type III or dysbetalipoproteinemia may be appropriate in a few patients. Measurement of *lipoprotein subclasses including IDL or remnant lipoproteins* is useful in research and can be helpful in some cases in managing patients.

HDL is classically defined in terms of its density range (1.063 to 1.21 g/mL) obtained by ultracentrifugation, which has been used as the standard by which the accuracy of other HDL methods is judged. However, the density range of Lp(a) (1.04 to 1.08 g/mL) overlaps that of HDL (see Table 26-4), so in patients with high Lp(a) concentrations ultracentrifugation at 1.063 g/mL would overestimate the true HDL concentration. As a consequence, the reference method, described previously, uses precipitation to separate HDL, similar to the approach commonly used for routine *determinations*.[326]

Precipitation Methods. HDL cholesterol has been most commonly measured (Box 26-5) in the supernatant solution after the precipitation of the apo B-100–containing lipoprotein directly from plasma or serum using agents such as polyanions in the presence of divalent cations.[104] The apo B-100–containing lipoproteins include VLDL, IDL, Lp(a), LDL, and, when present, chylomicrons (see Table 26-4). As indicated earlier, LDL and HDL are the largest contributors to total cholesterol in normal people, with LDL accounting for about two thirds and HDL for about one third of the total cholesterol. On average, IDL and Lp(a) each account for only about 2 to 3 mg/dL of the total cholesterol, although *their concentrations can be considerably higher in some* individuals.

BOX 26-5 Methods for HDL Separation/Quantification

Precipitation (1st generation)
- Heparin-Mn^{2+}
  - 0.46 mmol/L (LRC method)[78]
  - 0.92 mmol/L (recommended for EDTA plasma)[140]
- Dextran Sulfate (50 kDa) Mg^{2+}[221] (AACC Selected Method and DCM)
- Phosphotungstate-Mg^{2+}[136]

Facilitated Separation (2nd generation)
- Magnetic with/dextran sulfate-Mg^{2+}[143]

Homogeneous (3rd generation)
- Antibody four-reagent method[140] (International Reagents Corp)
- Polyethylene glycol modified enzymes w/cyclodextrin[146] (Kyowa Medex)
- Synthetic polymer/detergent[144] (Daiichi)
- Antibodies[153] (Wako)
- Catalase[154] (Denka Seiken)

Polyanions react with positively charged groups on lipoproteins; their action is facilitated in the presence of divalent cations, which interact with negatively charged groups, causing aggregation and a cloudy precipitate. Precipitation is usually complete within 10 to 15 minutes at room temperature; at 2 °C to 4 °C a 30-minute incubation period is preferred. The precipitate is then sedimented by centrifugation typically for 45,000 *g*-min (i.e., the equivalent of 1500×*g* for 30 minutes). Centrifugation at higher *g* forces, e.g., 10,000×*g* accelerates sedimentation and can actually improve complete precipitation of apo-B–containing particles. HDL cholesterol is then measured in the clear supernatant.

Several polyanion-divalent cation combinations have been used. Initially, heparin sulfate with $MnCl_2$ was adopted by the National Institutes of Health (NIH) and became common in research laboratories, which provided the rationale for employing this combination in the CDC RM. With the transition to enzymatic cholesterol assay methods, residual Mn^{2+} was found to interfere, giving artifactually high results. Techniques were devised to reduce this interference but necessitated additional manipulations, making them inconvenient for routine use. One approach was to add the chelator ethylenediaminetetraacetic acid (EDTA) to the cholesterol reagent to complex residual manganate.[290] Another was to add carbonate in a second precipitation step to precipitate excess Mn^{2+} from the heparin-Mn^{2+} supernatant.[20] Most laboratories avoided these tedious approaches, adopting methods using other precipitants to prevent interference by Mn^{2+} altogether. In time, variations of dextran sulfate or phosphotungstate with Mg^{2+} became most common.[323,238] A method using dextran sulfate with a molecular weight of 50 kDa was validated as a selected method and became the most common precipitation reagent in the United States.

There are several key issues in applying precipitation reagents to measure HDL cholesterol. First, the precipitability of lipoproteins with polyanions and divalent cations depends on the lipid and protein compositions of the molecules.[37] The greater the compositional differences, the more easily the lipoproteins are separated. Thus apo B-100–containing lipoproteins are more easily separated from HDL than they are from each other, and it is for this reason that precipitation methods have been more widely and successfully used for HDL analysis than for LDL or VLDL measurement.

Second, the various precipitants differ in their abilities to precipitate apo B-100–containing lipoprotein completely while leaving most species of HDL in solution,[18,238] resulting in the potential for biases between precipitation methods. With modern reagent-instrument-calibrator systems, conditions are generally optimized to produce values that closely approximate and are traceable to reference method values. But method-to-method biases are observed; however, they appear to be decreasing with experience, although significant discrepancies may be observed on individual specimens.

Third, the precipitation methods can be inaccurate under certain conditions. For example, precipitation of apo B-100–containing lipoprotein can be incomplete in samples with high concentrations of triglyceride-rich lipoproteins. The lipoprotein precipitate should be tightly packed after centrifugation, and the HDL-containing supernatant should be optically clear. Any turbidity at all indicates inadequate sedimentation of the apo B-100–containing lipoprotein, and even a small amount of unsedimented precipitate can produce a significant error in the HDL cholesterol measurement. Samples with high triglyceride concentrations (generally those above 400 mg/dL) frequently produce turbid supernatants because the triglycerides can reduce the density of the lipoprotein-precipitating reagent complex to the point that some of the complex remains unsedimented. In cases of extremely high triglyceride concentrations, some of the precipitate may even form a floating layer over a clear or turbid supernatant, in addition to the usual precipitate at the bottom of the centrifuge tube.

There are several ways to address this problem in hypertriglyceridemic specimens. First, the sample can be ultracentrifuged and the triglyceride-rich lipoprotein removed before precipitation as described for the reference method. Second, a sample with a turbid supernatant can sometimes be cleared by centrifuging for a longer time or at higher *g*-forces.[322] Third, the sample can be diluted to reduce the concentration of triglyceride-rich lipoproteins before the precipitant is added. In general, a dilution greater than twofold should not be used because higher dilutions can cause large dilution errors. This is a particular concern because hypertriglyceridemic patients tend to have low HDL cholesterol levels. A fourth approach is to pass the turbid supernatant through a 0.45-μm filter to remove the unsedimented precipitate before measuring cholesterol in the filtrate.[322]

Finally, matrix effects can influence the results. Matrix effects can arise from the nature of the sample itself or from the addition of anticoagulants or preservatives.[191] For example, HDL cholesterol measurements can be inaccurate, and usually are more variable when obtained from lyophilized samples than from fresh or frozen sera.

Additives including anticoagulants such as citrate and fluoride can have large osmotic effects that cause water to shift from the cells to the plasma. This dilutes the lipoprotein by 10% or more and produces erroneously low values. EDTA, traditionally the preferred anticoagulant for lipoprotein measurements, causes a slight dilution, but has been used because it also inhibits certain oxidative and other changes that can affect some lipoprotein or apolipoprotein measurements. Lipid and lipoprotein concentrations in EDTA plasma tend to be about 3% lower than in serum, an effect that may not be readily noticeable in HDL cholesterol measurements. EDTA, however, complexes some of the Mn^{2+} in the heparin-Mn^{2+} method, and it has been found necessary to use a higher concentration of $MnCl_2$ (0.092 mol/L, final concentration in the reaction system) when the procedure is

used with EDTA plasma than with serum (0.046 mol/L).[16,322] Heparin, by virtue of its high molecular weight and when present in concentrations used for anticoagulation, has no measurable effect on lipid or lipoprotein concentration, and does not affect HDL cholesterol measurements.

Second Generation Methods. A second generation dextran sulfate method (Box 26-5) reduces the interference associated with increased triglycerides (POLYMEDCO, Cortlandt Manor, N.Y.). With it, the dextran sulfate precipitant is complexed with magnetic particles, allowing the lipoprotein-precipitant-magnetic particle complex to be removed rapidly by placing the reaction vessel on a magnetic disk. HDL cholesterol is then measured in the usual way. The method can also be adapted for use in an automated clinical chemistry analyzer, allowing the supernatant to be analyzed without the necessity for removing it from the sedimented complex. The method was reported to have a bias of about 4% to 7% in the concentration range 30 to 50 mg/dL compared with ultracentrifugation combined with polyanion precipitation using a conventional dextran sulfate–Mg^{2+} method, and a coefficient of variation (CV) under 4%, similar to the usual dextran sulfate–Mg^{2+} method.[108,206]

Homogeneous Assays. A major breakthrough in HDL assays was reported in 1994,[128] with the introduction of the first of a series of so-called "homogeneous" immunoassay methods for lipoproteins (Box 26-5). Compared with the earlier precipitation methods requiring manual pretreatment steps, the homogeneous methods substantially improve workflow in the modern clinical laboratory, making sample handling as simple as placing a bar-coded specimen tube on the automated analyzer. Elimination of the manual steps provides cost savings with generally higher reagent costs offset by decreased labor costs. The fully automated methods also improve precision through more consistent pipetting of smaller specimen volumes and precise temperature control and reaction timing, which facilitate achieving the NCEP analytical performance goals. Evaluation studies have typically demonstrated substantially better precision, with CVs about half those of conventional pretreatment methods.

The first homogeneous assay for HDL cholesterol required four successive reagent additions (International Reagents Corp., Kobe, Japan). The first reagent contained polyethylene glycol, which causes aggregation of the apo B-100–containing chylomicrons, VLDL, and LDL. The second reagent protected or blocked the aggregated lipoproteins with antibodies to apo B-100 and apo C. The cholesterol reaction enzymes (cholesterol esterase, cholesterol oxidase, and peroxidase) were added in the third reagent, which acted upon only the unprotected HDL cholesterol. The fourth reagent stopped the color reaction and solubilized the aggregates with guanidine salts, clearing the reaction mixture for measurement of color. This breakthrough method, even though not suited for all analyzers because of the multiple reagent additions, was capable of full automation, paving the way for subsequent, two-reagent homogeneous methods.

In 1995, a second homogeneous method became available (Kyowa Medex Co., Tokyo[297]; Roche Diagnostics, Indianapolis) that used sulfated alpha-cyclodextrins together with Mg^{2+} to selectively block but not precipitate chylomicrons and VLDL, providing selectivity without the necessity for precipitation. Secondly, covalently linked polyethylene glycol molecules enhanced the specificities of the enzymes cholesterol esterase and cholesterol oxidase toward the cholesterol in HDL. Polyethylene glycol having an MW of 6000 Da is thought to optimize the specificities at concentrations lower than those used previously to precipitate lipoproteins, implying that the modified enzymes were able to distinguish the lipoprotein classes based on their size and/or charge. The result was a fully automated homogeneous assay with only two reagent additions that is applicable for use with many of the common chemistry analyzers. The original kit included the second enzyme-containing reagent in lyophilized form, necessitating reconstitution, but a modification introduced in mid1998 included both reagents in liquid form.[104] A third modification decreased the Mg^{2+} concentration, apparently to reduce carryover in pipetting.

A synthetic polymer together with a polyanion to block the non-HDL lipoproteins is used in a third homogeneous assay (Daiichi Pure Chemicals Co., Tokyo /Genzyme Corp., Cambridge, Mass.).[107,162,206] A detergent is then added that exposes only cholesterol in HDL to the enzymes, giving specificity for HDL-C. This method also requires two reagent additions, the first with the polyanion and polymer-blocking agents and the second with detergent, enzymes, and substrates. A subsequent modification provided both reagents in liquid form with other changes to improve specificity and decrease potential interference.[105,144,334] A third modification without Mg^{2+} has been reported.[63,121]

A fourth homogeneous assay is based on immunoinhibition and includes two reagents (Wako Pure Chemicals Industry, Osaka, Japan).[156,184,219] The first reagent contains an antibody to human apo B-100 that reacts with the apo B-100–containing lipoproteins, chylomicrons, VLDL, and LDL, blocking their reaction with the enzymes that are added in the second reagent. The current formulation includes both reagents in liquid form.

A fifth homogeneous method (Denka Seiken Co., Niigata, Japan/Polymedco Inc., Cortlandt Manor, N.Y./Randox Laboratories Limited, Crumlin, UK) allows cholesterol esterase and oxidase to react with lipoproteins other than HDL, generating peroxidase, which, in turn, is scavenged by the enzyme catalase.[205,219] An inhibitor of catalase and a surfactant in a second reagent specifically react with HDL cholesterol, producing color through the usual peroxidase sequence.

At least one instrument application for each of the homogeneous assays discussed previously in this chapter has qualified for certification by the CRMLN, implying at least the capability to achieve agreement with the RM. However, con-

ditions and especially calibration may be different on various instrument applications and many have not been evaluated. Thus certification for the reagents cannot be considered universally applicable to all distributor versions, instrument applications, and lots. Similarly, published evaluation studies have confirmed that the methods can be accurate but may not be so in every commercial application.[198] Laboratories choosing to adopt homogeneous assay applications that have not been certified by the CRMLN are encouraged to confirm that their particular systems are accurate. In addition, several more recent evaluations have noted that some homogeneous reagents may lack specificity or ruggedness, especially on specimens with unusual lipoprotein composition.[326]

Specificity and Interference. The accuracy of measuring HDL cholesterol in each individual specimen is a function not only of bias or overall inaccuracy related to calibration, but also of the ruggedness of the assays, their specificity for HDL cholesterol, and absence of interference by other lipoproteins and constituents of the specimen matrix. Laboratories supporting research studies and lipid clinics with a high proportion of atypical specimens must be especially concerned about this issue. The CRMLN certification studies and many published evaluation studies, assessing accuracy, include only samples from relatively normal subjects. Most studies did not determine performance in samples from patients with extreme hyperlipidemias, such as type III or other conditions, such as liver and kidney disease, which often result in unusual lipoproteins with atypical separation characteristics. Only a few studies have included such extreme specimens and have raised questions about the specificity of the homogeneous reagents.[91,113,142,280,319]

Most studies of interference have been fairly traditional and relatively modest.[11,108,119,144,205] Evaluations indicate that triglycerides below 900 mg/dL do not generally interfere with any of the methods and some methods are reportedly free of interference to nearly 2000 mg/dL. Hemoglobin below 2 g/L and bilirubin below 10 mg/dL do not interfere appreciably with any of the homogeneous methods.

Considerations in Choosing an High-Density Lipoprotein Method. Laboratories have had to consider the alternatives in deciding whether to replace a conventional pretreatment method with a homogeneous reagent: improved efficiency on the one hand versus occasional discrepant results on the other. Routine clinical laboratories tend to choose the fully automated methods, often because of unavoidable pressures to improve efficiency. Laboratories performing research and supporting lipid clinics, on the other hand, often choose to retain a conventional precipitation method. An important factor in the latter choice is that a laboratory supporting long-term studies cannot tolerate the potential changes and shifts in results that have occurred because of the frequent modifications in the homogeneous reagents.

Low-Density Lipoprotein Cholesterol

Methods for LDL cholesterol generally quantitate a so-called "broad-cut fraction" including not only the primary LDL species in the 1.019 to 1.063 kg/L density range, but also IDL, density 1.006 to 1.019 kg/L, and Lp(a).[208] Therefore the usual convention based on the following formula is an approximation accepted for convenience:

$$\text{Total cholesterol (chol)} = \text{VLDL chol} + \text{LDL chol} + \text{HDL chol} \quad (16)$$

LDL cholesterol can be measured using both indirect and direct methods, and either approach has been used in major studies that established the relationship between LDL cholesterol concentration and the risk for CHD.

Indirect Methods. Indirect methods for measuring LDL cholesterol are based on measuring a number of lipid-related analytes followed by their use in calculating the LDL cholesterol content of a specimen. This includes the use of the Friedewald equation and the beta-quantification method.

The Friedewald Equation. In the most widely used indirect method (Box 26-6), cholesterol, triglyceride, and HDL cholesterol are measured and LDL cholesterol is calculated from the primary measurements using the empirical equation of Friedewald and colleagues[84]

$$[\text{LDL chol}] = [\text{Total chol}] - [\text{HDL chol}] - [\text{Triglyceride}]/5 \quad (17)$$

where all concentrations are given in milligrams per deciliter (triglyceride/2.22 is used when LDL cholesterol is expressed in millimoles per liter). The factor [triglyceride]/5 is an estimate of VLDL cholesterol concentration, and is based on the average ratio of triglyceride to cholesterol in VLDL.

BOX 26-6 Methods for LDL Separation/Quantification

Beta-quantification
- Ultracentrifugation at density 1.006 Kg/L to float VLDL
- Precipitation with polyanion/cation for HDL
- LDL calculated as density >1.006 – HDL
- Most commonly used by specialty lipid laboratories

Calculation using Friedewald formula
- [LDL chol] = [Total chol] – [HDL chol] – [Triglyceride]/5
- Originally proposed for epidemiology studies
- Became the most common method in routine clinical labs

Homogeneous Reagents
- LDL solubilization (Kyowa Medex)
- LDL protected/deprotected by surfactants (Daiichi)
- LDL protected/catalase (Wako)
- Non-HDL catalase/LDL azide (Denka Seiken)
- LDL protected by Calixarene/cholesterol dehydrogenase (International Reagents Corp)

Several investigators have evaluated the accuracy of LDL cholesterol estimated with equation (17). For example, DeLong and colleagues recommended the use of the expression 0.16 × [triglyceride] as a better estimate of VLDL cholesterol, and consequently, the factor [triglyceride]/6 is used in a few laboratories.[65] Other factors have been suggested for particular populations,[238] but no single factor was accurate under all circumstances. However, when the original factor [triglyceride]/5 was compared with a combined ultracentrifugation-polyanion precipitation method in about 5000 samples, the errors in LDL cholesterol estimated with equation (17) were found to be symmetrically distributed about zero.[324] On balance, the NCEP recommended the use of the original factor [triglyceride/5] for estimating LDL cholesterol with equation (17).[238]

In practice, the Friedewald calculation is reasonably accurate, but there are several well known circumstances under which the Friedewald equation cannot be used. First, calculation is precluded in samples that have triglyceride concentrations above 400 mg/dL or in those that contain great amounts of chylomicrons (nonfasting specimen). At high triglyceride concentrations, the factor [triglyceride]/5 as an estimate of VLDL cholesterol concentration is not appropriate because such samples can also contain chylomicrons, chylomicron remnants, or VLDL remnants, all of which have higher triglyceride/cholesterol ratios. Under these circumstances, the use of the factor [triglyceride]/5 would overestimate VLDL cholesterol and therefore underestimate LDL cholesterol. The Friedewald equation has been found to be most accurate in samples with triglyceride levels below 200 mg/dL,[324] but the error becomes unacceptably large (i.e., >10%) at triglyceride concentrations greater than 400 mg/dL.

The opposite error can occur if the Friedewald equation is used in patients with type III hyperlipoproteinemia. Type III hyperlipoproteinemia is characterized in part by the presence of β-VLDL, not normally present in the blood. Biochemically, β-VLDL occurs in the VLDL, density range, but is much richer in cholesterol than normal VLDL with a ratio of triglyceride/cholesterol on the order of 3:1. Application of the factor [triglyceride]/5 in type IIIs would underestimate VLDL cholesterol and in turn overestimate LDL cholesterol. Thus a patient with type III hyperlipoproteinemia may appear to have an artifactually high LDL cholesterol concentration.

Fortunately, both of these conditions are uncommon. The 95th percentile for fasting plasma triglycerides in the United States is below 300 mg/dL, indicating that only a small percentage of specimens will exceed the 400 mg/dL cutoff. Plasma from fasting subjects does not normally contain chylomicrons, and even if present, chylomicrons can be observed visually as a floating "cream" layer in samples that have been allowed to stand undisturbed at 4 °C overnight. Finally the prevalence of type III hyperlipoproteinemia is only about 1 to 2 per 1000 persons in the general population.[153] Thus the Friedewald calculation will be reasonably reliable in the majority of patients.

Beta-Quantification (Ultracentrifugation-Polyanion Precipitation). This method is the precursor to the HDL and LDL reference methods and is often used in samples for which the Friedewald equation is inappropriate. It follows the procedure used in the LRC Program and combines preparative ultracentrifugation and polyanion precipitation.[104] To use the assay, an accurately measured aliquot of plasma is first ultracentrifuged at 105,000×*g* for 18 hours at 10 °C to a density of 1.006 g/mL (plasma density). Under these conditions, VLDL and, if present, chylomicrons and β-VLDL, accumulate in a floating layer, with the infranatant containing primarily LDL and HDL (Figure 26-26) plus any IDL and Lp(a) that may be present. The floating layer, removed with the aid of a tube slicer, is sometimes analyzed as a check on recovery and may be saved for electrophoretic analysis. The infranatant solution is remixed, reconstituted to known volume, and its cholesterol content measured. HDL cholesterol is usually measured in a separate aliquot of plasma, but when necessary, an aliquot of the d 1.006 g/mL infranatant can be treated to remove the apo B-100–containing lipoproteins [IDL, LDL, and Lp(a)], and the HDL cholesterol then measured in the clear supernatant. VLDL and LDL cholesterol are calculated as follows:

$$[\text{VLDL chol}] = [\text{Total chol}] - [\text{d} > 1.006\ \text{g/mL chol}] \quad (18)$$

$$[\text{LDL chol}] = [\text{d} > 1.006\ \text{g/mL chol}] - [\text{HDL chol}] \quad (19)$$

LDL cholesterol measured in this way is unaffected by the presence of either chylomicrons or other triglyceride-rich lipoproteins, or by β-VLDL. VLDL cholesterol is usually calculated from equation (18) rather than measured directly in the ultracentrifugal supernatant because it can be difficult to recover this fraction quantitatively, particularly when triglyceride concentrations are high.

Lipoproteins Included in the "LDL Cholesterol" Measurement. From the preceding discussion, it is obvious that in both methods, the term "LDL cholesterol" includes the contributions of cholesterol in the IDL and Lp(a) fractions and that in the core LDL. Although IDL and Lp(a) cholesterol usually contribute only a few milligrams per deciliter to the "total LDL cholesterol" measurement, their contributions can be significant in patients with high IDL or Lp(a) concentrations. For example, assuming that cholesterol (i.e., sterol nucleus) constitutes about 30% of the mass of Lp(a), it can be calculated that the Lp(a) cholesterol concentration would contribute about 12 mg/dL, or about 12%, to the LDL cholesterol measurement in a patient with an Lp(a) concentration of 40 mg/dL and an apparent LDL cholesterol concentration of 100 mg/dL. It has been suggested that a more specific measure of LDL cholesterol could be obtained by correcting the measured LDL cholesterol value for the contribution of Lp(a) cholesterol,[126,267] and a similar argument might be made for IDL. Increased concentrations of both IDL and Lp(a) appear to be related to the increased risk for CHD [see later section on Lp(a)], however, and although such corrections might increase the specificity of the methods for LDL cholesterol, per se, they might also give

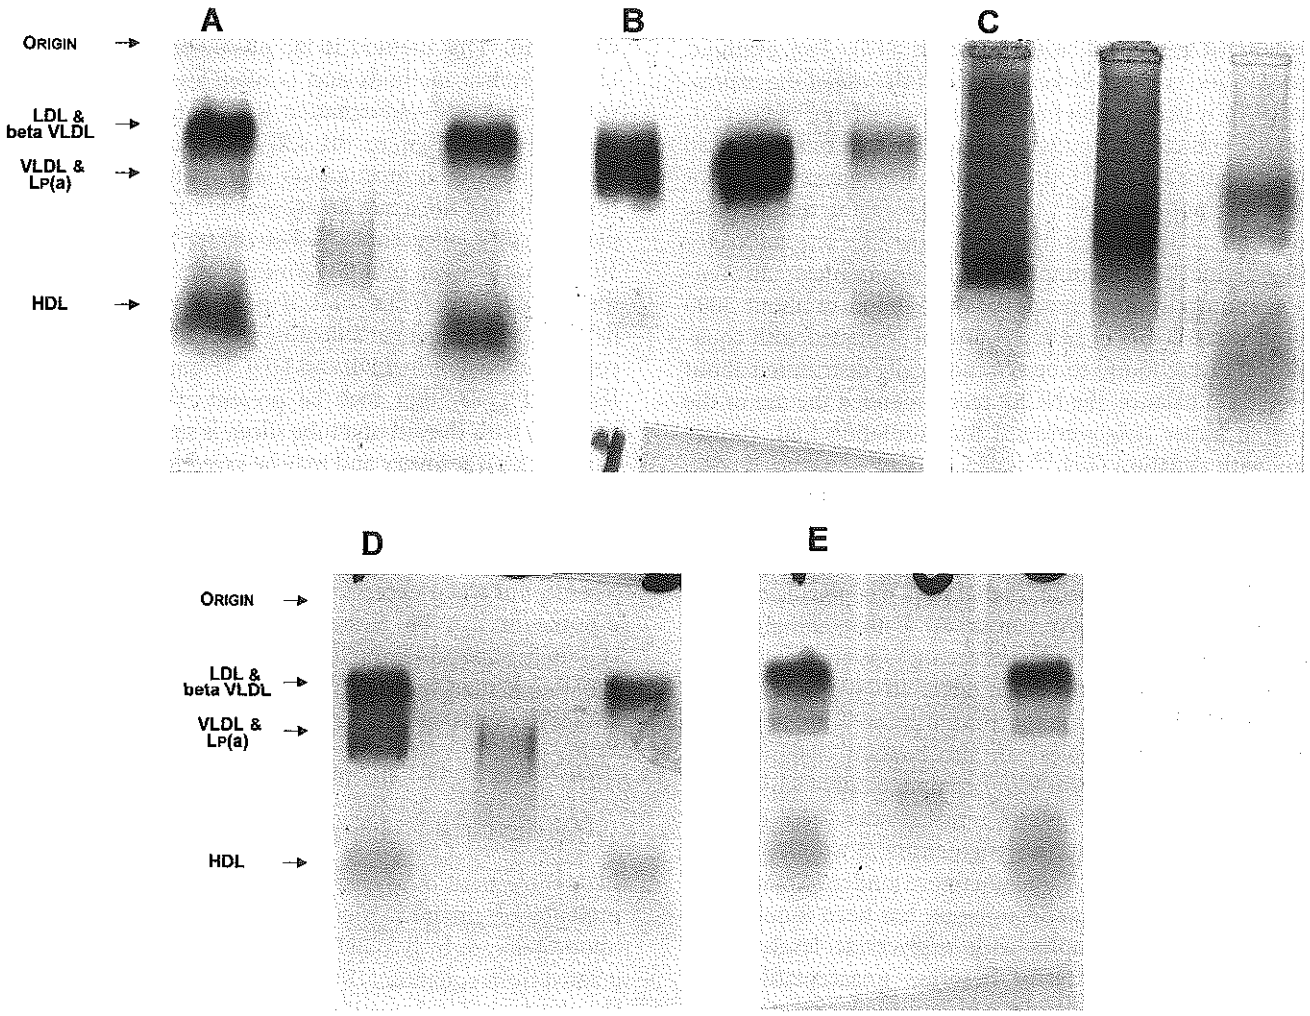

Figure 26-26 Agarose gel electrophoresis of plasma lipoprotein. In each photograph, the samples were applied in the following order, reading left to right: unfractionated plasma, ultracentrifugal density 1.006 g/mL supernatant solution, ultracentrifugal infranatant solution. **A,** Pattern seen in normal samples and samples with high LDL cholesterol concentrations. **B,** Type III hyperlipoproteinemia pattern. **C,** Severe hypertriglyceridemia, triglyceride = 3840 mg/dL. Note chylomicrons at origin. **D,** Pattern observed in samples with moderately elevated triglyceride, triglyceride = 281 mg/dL, LDL cholesterol = 145 mg/dL. Note absence of chylomicrons. **E,** Pattern observed in patients with high concentrations of Lp(a). Note presence of Lp(a) found in infranatant solution. This sample had an Lp(a) concentration of 77 mg/dL. *LDL,* Low-density lipoprotein; *VLDL,* very low-density lipoprotein; Lp(a), lipoprotein(a); *HDL,* high-density lipoprotein.

LDL cholesterol values that underestimate cardiovascular risk because they exclude some of the atherogenic lipoproteins. Moreover, this might occur more frequently with patients with CHD or who are at risk for CHD based on their "LDL cholesterol" concentrations. Consequently, the NCEP Working Group on LDL cholesterol measurement suggested that LDL cholesterol values should *not* be corrected for the contribution of other atherogenic lipoproteins, and also recommended that further research be conducted to establish the individual contributions of IDL, Lp(a), and LDL cholesterol to the CHD risk as reflected in current LDL cholesterol measurements that include all three lipoprotein classes. The most recent guidelines from the NCEP expand on this concept by introducing the term "non-HDL cholesterol," which includes all of the apo B-100–containing atherogenic lipoproteins including not only Lp(a) and IDL but also VLDL cholesterol.[77]

Diagnosis of the Type III Lipoprotein Pattern. The ratio of VLDL cholesterol to plasma triglyceride, expressed in terms of mass, is 0.2 or lower in normal samples and in those from patients with lipoprotein disorders other than type III hyperlipidemia. In type III hyperlipoproteinemia, the ratio is 0.3 or higher because of the presence of β-VLDL, and the elevated ratio can persist even after treatment.

In addition, β-VLDL can also be observed directly by subjecting the VLDL fraction to agarose gel electrophoresis, where it migrates electrophoretically with LDL rather than VLDL (see Figure 26-26). The combination of a VLDL cholesterol/plasma triglyceride ratio of 0.3 or higher and the observation of β-VLDL in the ultracentrifugal supernatant establishes the type III lipoprotein pattern.

Direct Methods. Selective precipitation and homogeneous immunoassay methods have been used to measure LDL cholesterol directly.

Selective Precipitation. Several direct methods have been used for LDL cholesterol measurement that are based on selective precipitation with polyvinyl sulfate or heparin at low pH.[123,165,195] LDL cholesterol is then calculated as the difference between total cholesterol and that in the supernatant, or in another variation, directly in the LDL precipitate. It is not clear whether atherogenic lipoproteins other than LDL itself are also detected, and these methods might be expected to be subject to similar sources of error as those encountered with precipitation methods for HDL separation. A more specific method used a mixture of polyclonal antibodies to apo A-I and apo E linked to a resin to bind VLDL, IDL, and HDL, with LDL cholesterol measured in a filtrate by the usual methods. The method was reasonably precise and in good agreement with ultracentrifugation-polyanion precipitation.[109,123,186,230] The reagent was in commercial distribution for several years but, requiring a separate pretreatment step, was eventually superseded by a new class of direct homogeneous reagents patterned after the homogeneous reagents for HDL cholesterol.

Homogeneous Assays. Following the approach similar to those used with the homogeneous methods for HDL cholesterol,[326] homogeneous assays have been developed to measure LDL cholesterol. For example, five homogeneous LDL methods are commercially available (Box 26-6) and differ by containing different detergents and other chemicals, which allow specific blocking or solubilization of lipoprotein classes to achieve specificity for LDL cholesterol. All suppliers offer kits with two reagents, readily adaptable to most clinical chemistry analyzers.

Sugiuchi and colleagues developed the first homogeneous method for measuring LDL cholesterol[296]; the reagent is distributed by Kyowa Medex, Tokyo and Roche Diagnostics, Indianapolis. With this method, LDL is directly measured by suppressing the other lipoproteins (the other four methods suppress LDL first and react with other lipoproteins before determining LDL cholesterol). The method is formulated in two reagents. The first has $MgCl_2$, dye, buffer (pH 6.75), and the α-cyclodextrin sulfate,[297] which has a highly concentrated negative charge to mask cholesterol in chylomicrons and VLDL in the presence of magnesium ions.[296] The second reagent includes the enzymes cholesterol oxidase and cholesterol esterase, peroxidase, dye, buffer (pH 6.75), and a polyoxyethylene-polyoxypropylene polyether (POE-POP) to block cholesterol, especially in HDL.[296,297] The molecular mass of the POP in the POE-POP molecule and the hydrophobicity index determine selectivity to LDL; 3850 Da was demonstrated to be optimum.[297]

A second method also is formulated in two reagent variations (Daiichi Pure Chemicals Co., Tokyo; Genzyme Diagnostics, Cambridge, Mass.). The first reagent contains ascorbic acid oxidase, 4-aminoantipyrine, peroxidase, cholesterol oxidase, cholesterol esterase, buffer (pH 6.3), and a detergent, which solubilizes all non-LDL lipoproteins, allowing reaction of their cholesterol with the esterase and oxidase enzymes, forming a colorless product. The second reagent contains N,N-bis-(4-sulfobutyl)-m-toluidine Na_2 (DSBmT), buffer (pH 6.3), and a detergent to specifically release LDL cholesterol. The resulting hydrogen peroxide reacts with N,N′-bis-(4-sulfobutyl)-M-toluidine disodium salt to generate a colored product.

A third method (Wako Chemicals, Osaka, Japan) includes a reagent with Good's buffer (pH 6.8), (N-(2-hydroxy-3-sulfopropyl)-3,5-dimethoxyaniline, sodium salt), cholesterol esterase, cholesterol oxidase, catalase, polyanions, and amphoteric surfactants, the latter selectively protecting LDL from enzymatic reaction. The non-LDL cholesterol reacts with esterase and oxidase, producing hydrogen peroxide, which is consumed by catalase. The second reagent includes Good's buffer (pH 7.0), 4-aminoantipyrene, peroxidase, sodium azide, and a de-protecting reagent, which removes the protecting agent from LDL, enabling the specific reaction of cholesterol esterase and cholesterol oxidase with its cholesterol, producing hydrogen peroxide and a blue color complex.[75,189]

Non-LDL cholesterol is removed in a fourth method (Denka Seiken, Niigata, Japan/Polymedco Inc., Cortlandt Manor, N.Y.) via a selective reaction with cholesterol oxidase and cholesterol esterase with the resulting peroxide byproduct eliminated by reaction with catalase (CAT). In this two reagent method, the first reagent contains $MgCl_2$, cholesterol esterase, cholesterol oxidase, catalase, and N-(2-hydroxy-3-sulfopropyl)-3,5-dimethoxyaniline sodium salt, Emulgen 66 (polyoxyethylene compound; Kao), and Emulgen 90, both nonionic surfactants, in Good's buffer (PIPES; 100 mmol/L; pH 7.0). Its second reagent contains peroxidase, 4-aminoantipyrine, sodium azide (to inhibit the catalase), and Triton X-100 in Good's buffer. The hydrophilic/lipophilic balance of the detergents is chosen to obtain appropriate selectivity to the lipoproteins.[218]

In a fifth method (International Reagents Corp., Kokusai-Kobe, Japan), its first reagent contains the detergent calixarene that converts LDL to a soluble complex. Cholesterol esters of HDL-C and VLDL-C are preferentially hydrolyzed by a cholesterol esterase (chromobacterium), cholesterol oxidase, and hydrazine, which divert the accessible cholesterol to cholestenone hydrazone. A second reagent with deoxycholate breaks up the LDL-calixarene complex, allowing LDL-C to react with the esterase, a dehydrogenase, and β-NAD to yield cholestenone and ß-NADH, the latter measured by a spectrophotometer.

Analytical Performance of LDL Methods. Evaluations of the LDL homogeneous assays indicate that CVs are gen-

TABLE 26-23 Analytical Performance of Homogeneous LDL-C Assays

	Imprecision (CVs)	Dynamic range (mg/L)	Recovery (%)			Accuracy	
			LDL	VLDL	IDL	bias (%)	bias (mg/L)
Kyowa	0.7-3.1	2-4100	97-105	16	52-64	0.8-11.2	−60 to −80
Daiichi	<3.1	4-10,000	87	19	31-47	3.9-5.1	−48 to −80
Wako	≤1.2	10-3000	—	—	—	0.4	−15
Denka	<1.8	70-5500	95	10	31	—	—
IRC	≤0.6	?-4000	—	—	—	—	—

erally <3% and consistently within the NCEP performance target of <4% CV (Table 26-23). By contrast, CVs for the Friedewald calculation have been estimated to approximate 4% in expert laboratories and as high as 12% in routine clinical laboratories, estimated from proficiency surveys.[208]

With regard to accuracy, all of the homogeneous assays have qualified for certification through the CRMLN program, suggesting agreement with the reference methods at least in relatively normal specimens. Nevertheless, as indicated previously for HDL cholesterol methods, there are many instrument applications and not all have been evaluated for bias. Factors such as lot-to-lot differences, unique calibrations by distributors, different calibrations from country to country, and reformulations of reagents might affect actual biases.[326] In a 2002 study, four homogeneous assays were compared with the LDL RM; unacceptable total error was found and the authors recommended caution in adopting the methods.[192]

In addition to overall accuracy, primarily a function of calibration, methods should be specific for the LDL-C fraction; this is of particular concern considering the heterogeneity of the lipoproteins. Published studies suggest that the homogeneous assays interact unequally with the different components of the "broad-cut LDL": LDL subclasses, IDL, Lp(a), and Lp-X.* A 2002 study of two homogenous reagents using isolated lipoprotein fractions confirmed the lack of specificity for VLDL and LDL subclasses.[309] The two homogeneous methods included about 20% of isolated VLDL. Also the reagents missed about 30% of IDL and up to 50% of the isolated LDL fractions, especially the important smaller and more atherogenic subclasses. The inclusion of some VLDL will offset the loss of LDL fractions, so the lack of specificity may not be obvious in relatively normal specimens. However, the lack of specificity for lipoprotein subclasses and differences among reagents may make the measured results for each individual different depending on the particular lipoprotein profile and the reagent. Obviously the homogeneous LDL cholesterol assays have to be more rigorously evaluated in other than normal specimens before they can be recommended with confidence.

*References 75, 78, 118, 218, 259, 266, 296.

Conventional interference studies have demonstrated that the methods are not subject to significant interference from bilirubin and hemoglobin. However, higher levels of triglycerides have been shown to interfere, increasing apparent LDL cholesterol values, not surprising considering the reported lack of specificity for VLDL.[118,204,218] Alternately the sulfated α-cyclodextrin used in the Sugiuchi assay to block VLDL cholesterol appeared to cause underestimation of the LDL cholesterol.[75,207,296]

A major potential advantage of the homogeneous methods over the Friedewald calculation is the ability to use nonfasting specimens, convenient in managing patients. Results, judged by mean differences between paired fasting and nonfasting specimens, were promising, but patient classification was poorer with nonfasting specimens.[207,218,335] Lipoprotein composition is affected by recent diet; changes have been observed even with the more robust ultracentrifugation method. However, the changes in vivo are small and the convenience of being able to use nonfasting specimens may offset minor effects on accuracy. Nevertheless, until the use of nonfasting specimens is validated by more comprehensive studies, laboratories are encouraged to specify fasting.

Other Considerations in Adopting a Homogeneous LDL Method. Clinical laboratories are faced with the decision whether to implement the fully automated homogeneous methods for LDL cholesterol, either replacing or supplementing the traditional Friedewald calculation. The considerations are certainly not as compelling for the homogeneous LDL methods as for HDL. Even given the technical disadvantages of the Friedewald method: (1) the necessity for fasting, (2) the poor precision from the cumulative variations in the three underlying measurements, and (3) the well-known limitations in certain patients, it is firmly entrenched in routine practice and will likely be displaced only if the homogeneous methods can demonstrate clear advantages, for example, substantially better analytical performance or overall improved cost effectiveness in characterizing or monitoring patients, advantages that have yet to be shown. A 2002 review suggests that the homogeneous assays can only be recommended to supplement calculation for those patients with elevated triglycerides or other conditions precluding calculation.[208]

Oxidized LDL

In 1983 Brown and Goldstein reported that circulating LDL must undergo some structural modification before it becomes fully proatherogenic.[33] Patients who completely lack LDL receptors accumulate large amounts of cholesterol in their macrophages and form foam cells. The receptors, which recognize the modified LDL, were termed "the scavenger receptors."[88] Currently, several modifications that enhance the uptake of LDL by macrophages in vitro have been described, such as glycation, self-aggregation, immune complex formation, hydrolysis, and oxidation, with the latter receiving the greatest attention.[291]

LDL is oxidized in microdomains in the arterial wall where it is sequestered by proteoglycans and other extracellular matrix constituents and protected from plasma antioxidants. This process is a free-radical–driven lipid peroxidation chain reaction that is initiated by the free radical attacking the double bond associated with PUFA, leading to the generation of malonedialdehyde and 4-hydroxynonenal.[1] These intermediate compounds then bind to apo B-100, giving it an increased net negative charge and rendering it unrecognizable by native LDL receptors.

Oxidized LDL (oxLDL) has several proatherogenic properties including the rapid uptake by macrophages to form foam cells, chemoattraction for circulating monocytes, promotion of the differentiation of monocytes into tissue macrophages, and inhibition of the motility of resident macrophages.[291] It is also cytotoxic to several types of cells and immunogenic. Laboratory, clinical, and epidemiological studies have shown that this oxidation does also occur in vivo. Extracted LDL from human atherosclerotic lesions was shown to be oxidatively modified; circulating anti-oxLDL antibodies were detected in serum, with the titers correlating with progression of atherosclerotic lesions; and the use of various antioxidants (vitamin E and probucol among others) delayed the progression of atherosclerotic lesions.

A commercial enzyme-linked immunosorbent assay (ELISA) method for the determination of oxLDL is currently available (Mercodia).[115] However, at the present time the clinical relevance of oxLDL has not been established and therefore its routine measurement is not recommended.

Total Lipoproteins and Lipoprotein Subclasses

Several approaches have been used to quantitate all of the lipoproteins, and in some cases lipoprotein subclasses, in a single procedure. Nuclear magnetic resonance (NMR) spectroscopy is one of the more efficient methods,[221,222] detecting lipoprotein-associated fatty acyl methyl and methylene groups. The signals from subfractions of VLDL, LDL, and HDL can be resolved mathematically with values reported in terms of lipoprotein cholesterol concentrations based on assumptions about the average cholesterol compositions of the various classes of lipoproteins. A sample can be analyzed quickly using a small volume of serum by the method, which can be automated. A disadvantage of NMR is the inability to distinguish Lp(a) from LDL particles of the same size. Furthermore, the requirement for expensive specialized equipment and expertise limits application.

Density gradient ultracentrifugation is used to measure lipoprotein subclasses; it is performed in a vertical rotor with measurement of cholesterol continuously in the fractions eluted from the gradient.[47-49,53,276] Mathematical curve resolution derives the component lipoprotein profiles and allows calculation of their cholesterol concentrations. The method can determine concentrations of VLDL, IDL, LDL, Lp(a), and HDL cholesterol. LDL cholesterol subclasses can be expressed separately or combined to give a measurement similar to that provided by the Friedewald equation or beta-quantification. A disadvantage is that the procedure is technically demanding and requires instrumentation not usually available in clinical laboratories.

Lipoproteins have also been fractionated by gradient gel electrophoresis with several commercial applications. The electropherogram is scanned densitometrically and the areas under the various lipoprotein peaks are integrated and converted to equivalent lipoprotein cholesterol concentrations using assumed average cholesterol compositions for the lipoprotein. Resolution of the lipoprotein classes is better with gradient gel electrophoresis than with conventional agarose electrophoresis, but electrophoretic quantitation of lipoproteins in unfractionated samples has not gained wide acceptance because of the inherent limitations of such methods,[15,33] including the incomplete resolution of VLDL and LDL, the comigration of β-VLDL with LDL and Lp(a) with VLDL, differences in staining intensity of the lipoproteins, and other methodological challenges. The use of gradient gel electrophoresis for quantitative measurements has been useful in research but not widely used in routine practice.

None of the lipoprotein methods described in this section has been used widely enough to have been validated in independent studies to the same extent as have been the Friedewald and beta-quantification methods. In most cases, the identities of the lipoprotein contributing to the "LDL cholesterol" measurement have not been adequately established. Further evaluations should better define the relationships between these new methods and current reference and routine methods.

Intermediate-Density (Remnant) Lipoproteins

Remnant lipoproteins include the lipolytic products of catabolism of the triglyceride-rich lipoproteins, VLDL and chylomicrons, occurring in the VLDL and LDL ranges. A traditionally defined fraction at the lighter end of the LDL density range, the IDL portion comprises the 1.006 to 1.019 g/mL fraction, which is obtained by sequential ultracentrifugation for quantitation, generally in terms of cholesterol content.

Clinically, remnant lipoproteins have been shown to be predictive of the CHD risk.[110] A method for measuring a remnant fraction designated RLP cholesterol for remnant-like particles (RLP) has become commercially available,

using specific antibodies to separate a fraction of lipoprotein remnants. This fraction seems to be particularly indicative of conditions conferring increased CHD risk.[157,187]

Desktop Analyzer Methods

Portable analyzers, also called "desktop analyzers," "physician's office analyzers," or "point-of-care (POC) analyzers," have been developed for use in nonlaboratory settings (see Chapters 4, 10, and 11). Several such devices are capable of measuring cholesterol and most also quantify triglycerides and HDL cholesterol, with calculation of LDL cholesterol, in a few microliters of whole blood, serum, or plasma within a few minutes.

Sources of Variation in Lipid and Lipoprotein Measurements

Lipid and lipoprotein concentrations vary within individuals when measured on several occasions over time. The sources of variation can be broadly categorized as analytical and physiological. Analytical variations are inherent in the measurements themselves and arise from variations in sample collection procedures, volume measurements, instrument function, reagent formulations, uncertainties in the assignment of values to calibration materials, and other such factors. Normal physiological variation occurs independently of analytical error and reflects the actual changes in concentration that occur through the course of normal, day-to-day living. Such variations result from factors such as change in posture, which causes the redistribution of water between the vascular and nonvascular space, thereby changing the concentrations of nondiffusible plasma components.[19,190] Recent food intake produces transient increases in plasma triglycerides of 50% or more and decreases of up to 10% or 15% in LDL and HDL cholesterol depending on the fat content of the meal.[50,51,331] The shifts result from changes in the lipid composition of the lipoproteins that occur as chylomicrons are metabolized. Seasonal changes have also been observed, probably resulting from changes in dietary and exercise patterns throughout the year.[38,92] Normal physiological variations tend to occur in both directions, causing the lipid or lipoprotein concentration to vary somewhat about a mean value for a particular patient. Other kinds of physiological conditions cause changes from the patient's usual steady-state concentrations, for example, acute illness or stress, pregnancy, dietary changes that result in weight loss or gain, changes in saturated fat intake, or the effects of treatment with lipid-lowering medications. In these cases the changes tend to be in one direction, and they are not considered normal physiological fluctuations. Lipoprotein concentrations eventually return to the original steady-state levels when the patient recovers, or a new steady-state level is achieved.

Because normal physiological variations occur, it is difficult to evaluate a patient based on a single measurement because it applies only to the current sample. It is more appropriate to consider the patient's usual range of concentrations, or his or her average steady-state concentration. This distinction is more than academic because it is the basis of a twofold goal of lipid and lipoprotein measurement. From the laboratory's standpoint, the aim is to provide accurate measurements in the particular sample being measured. For this reason, the laboratory is primarily concerned with minimizing analytical error. From the physician's standpoint, however, the goal is to establish the patient's usual range of concentration for purposes of diagnosis and judging the effects of treatment. This aim is affected primarily by physiological variation because physiological variation contributes the larger proportion of the specimen-to-specimen variation observed in serial samples from the same patient. Some sources of physiological variation, such as posture during blood sampling, can be controlled and other factors that cannot be controlled, such as pregnancy, have to be considered in interpreting laboratory results.

Analytical Variation

Table 26-24 illustrates the current overall variation of lipid and lipoprotein measurements in about 4500 laboratories participating in a large, ongoing proficiency survey in 2003. The laboratories used a variety of methods and instruments. For total cholesterol measured with all methods in all laboratories, the average bias was in the range of −0.5% to −2.7% and the CVs were about 3.5%. These numbers represent the total of within- and among-laboratory components of variation, and suggest that reliable cholesterol measurements can be provided by most clinical laboratories. Similarly, the average bias for HDL cholesterol ranged from −3.9% to +4.4%, with overall CVs of about 6%. These results are remarkable because at HDL cholesterol concentrations above 42 mg/dL, they conform to current NCEP recommendations for acceptable HDL cholesterol measurements in single laboratories,[238] and for total cholesterol they meet NCEP criteria for acceptable measurements in single laboratories.[237]

The overall CVs are slightly higher for triglycerides, probably because of the contribution of triglyceride blanks and the inherent greater variability in triglyceride methods, but the bias has improved considerably in recent years. The performance in the calculated LDL cholesterol values is encouraging and reflects the improvement in the reliability of the primary measurements. Data are also now available for the measured LDL cholesterol. Both the overall CV and bias for the measured LDL cholesterol are inferior to those of the calculated values.

Physiological Variation

The normal physiological component of variation is calculated from the total variation of measurements in serial specimens from the same patients, after adjusting for analytical variation.[27,106,127,177,194] Such estimates differ somewhat from study to study, but after an extensive review of the literature,[237,238] the NCEP panels concerned with lipid and lipoprotein measurement assumed average physiological

§Friedewald equation using [triglyceride/5] as an estimate of very low-density lipoprotein cholesterol concentration.

CVs (Table 26-25). A wide variety of factors contribute to the physiological variations (Table 26-26). The physiological variations observed for cholesterol, HDL cholesterol, and LDL cholesterol are similar. Physiological variation for triglyceride is considerably higher because fasting triglyceride concentrations can vary widely within an individual. Coefficients of analytical variation in a well-controlled laboratory are considerably smaller, generally about 2% to 3% for cholesterol and triglycerides, and 4% to 5% for LDL and HDL cholesterol. It can be calculated that, on average, physiological variations contribute about 70% to 98% of the overall variance of lipid and lipoprotein concentrations in people sampled on several occasions (see Table 26-25). For this reason, a patient's usual lipid or lipoprotein concentration cannot be reliably established from a single measurement. NCEP guidelines recommend that for cholesterol, the average of measurements in two serial samples obtained at least 1 week apart be used; two to three serial specimens are recommended if feasible for triglyceride and HDL and LDL cholesterol.[238]

TABLE 26-25 Physiological Variation of Lipid and Lipoprotein Concentrations in Serial Specimens from the Same Individuals

Component	Physiological Variation (% CV)	Percentage of Variance Contributed by Physiological Variation*

NCEP Recommendations for Lipid and Lipoprotein Measurements

The following information has been summarized from the NCEP recommendations for lipid and lipoprotein measurement.[237,238]

1. *Database linkage.* Laboratories that provide lipid and lipoprotein measurements should maintain linkage with the existing epidemiological databases relating lipid and lipoprotein concentration to the risk for CHD. Because these databases have been established largely based on CDC standardized methods, the methods used for cholesterol, triglycerides, HDL cholesterol, and LDL cholesterol should give results equivalent to those used to establish those databases. Accordingly, CDC reference methods for cholesterol, triglycerides, and HDL cholesterol serve as the basis for judging the accuracy of other methods.
2. *Reference methods.* Reference methods should provide serum equivalent values.
3. *Routine methods.* In most cases, lipid and lipoprotein measurements can be made using specimens of either serum or plasma. Measurements in EDTA plasma can be converted to serum-equivalent values using the following equation:

$$\text{Equivalent serum value} = \text{Plasma value} \times 1.03 \quad (20)$$

4. *Cholesterol measurements.* In practice, either a fasting or nonfasting sample is used for cholesterol measurements. Triglycerides, HDL cholesterol, and LDL cholesterol measurements should preferably be made in samples collected after a 12-hour fast. As a convenience to the patient, such measurements are made after a 9-hour fast without introducing unduly large errors into the measurements.
5. *Blood samples.* Blood samples should be standardized to be taken in the seated position whenever possible. If this is not feasible, the patient should be sampled in the same position on each occasion.
6. *Specimen storage.* Serum or plasma should be removed from cells within 3 hours of venipuncture. Specimens can be stored for up to 3 days at 4 °C; up to several weeks at −20 °C in a nonself-defrosting freezer; and at −70 °C or lower for longer periods.
7. *Serial samples.* Using the mean of several serial measurements for clinical decisions averages out the effects of physiological and analytical variation. Measurements should therefore be made in at least two serial samples collected at least 1 week apart with the values averaged. Three serial samples are preferred for triglycerides, HDL cholesterol, and LDL cholesterol measurements, but two serial specimens can be used if necessary.
8. *Glycerol blanking.* The NCEP Working Group on Lipoprotein Measurement endorses the following recommendations, adapted from the Lipids and Lipoproteins Division of the American Association for Clinical Chemistry:
   - All laboratories should offer a glycerol-blanked triglyceride analysis, even though it may be performed only when requested. Any specimen with triglycerides >200 mg/dL (2.26 mmol/L) should be glycerol blanked using a "reflex" ordering system.
   - Reports from the laboratory should clearly state whether the triglyceride analysis was glycerol blanked (e.g., designated as "Blanked Triglyceride" or "Unblanked Triglyceride"). Physicians need to be educated as to how the inclusion of a glycerol blank may alter the meaning of the results.
   - Glycerol blanking of triglyceride measurements must be done in laboratories participating in the CDC Lipoprotein Standardization Program and is recommended for laboratories that specialize in assessment of lipid status, have large populations of hyperlipidemic subjects, or participate in clinical or basic research.
   - Glycerol blanking of triglyceride analyses does not have to be routinely conducted on outpatient samples unless economically feasible. However, because of the potential for higher glycerol concentrations in hospital inpatient specimens, all inpatient specimens should be routinely glycerol blanked.
9. *Goals for analytical performance.* The NCEP goals for analytical performance differ slightly from CDC standardization criteria because NCEP goals are stated in terms of total error, which reflects both bias and imprecision,[238] whereas CDC standardization criteria consider each separately. NCEP recommendations for total error are shown in Table 26-27.

These guidelines were established after considering levels of accuracy and imprecision that are achievable in well-controlled research and clinical laboratories.[238] A laboratory can approximate its conformance to the total error recommendations using the following equation:

$$\text{Total error} = \%\,\text{Bias} + 1.96\,(\text{CVa}) \quad (21)$$

TC, Total cholesterol; *HDL-C*, high-density lipoprotein cholesterol; *TG*, triglycerides; *LDL-C*, low-density lipoprotein cholesterol; +, minimal to moderate increase; ++, moderate to high increase; –, minimal to moderate decrease; —, moderate to high decrease; *NC*, essentially no change or trend.

where % bias is the mean laboratory difference between the measured value for a serum control pool and the reference value for the pool, and CVa is the overall analytical CV for the pool, including within and among run variations, and calculated as:

$$\frac{\text{Standard deviation}}{\text{Laboratory mean}} \times 100 \qquad (22)$$

Bias should be calculated as the difference from reference values rather than from manufacturers' stated values when these differ.

The individual biases and CVs shown in Table 26-27 should be viewed as examples of conditions under which the total error criteria can be met. A laboratory with less bias can tolerate slightly greater imprecision without exceeding the total error criteria. Conversely, imprecision must be lower if

TABLE 26-27 National Cholesterol Education Program Recommendations for Analytical Performance of Lipid and Lipoprotein Measurements

	Total Error (%)	Consistent With	
		Bias (%)	CV (%)

†Maximum allowable.
‡CVs shown apply at HDL cholesterol concentrations greater than 40 mg/dL. At lower concentrations, the precision criteria are based on standard deviation. Acceptable standard deviation is 2.0 mg/dL by July, 1997 and 1.7 mg/dL by 1998.

bias increases. For example, a laboratory operating with a bias of 3% and a CV of 3% for cholesterol would have a total error of 3% + (1.96 × 3%), or 8.9%. If, however, bias is only 1%, the CV could be as high as 4% without exceeding the criteria for total error [1% + (1.96 × 4%) = 8.8%]. (In practice, many laboratories can achieve total errors under 6%, assuming a bias of 2% and CV of 2%.)

It is important to note that the NCEP panels considered that the physician usually does not distinguish between lipid and lipoprotein measurements on the basis of the methodology used to make the measurements. For this reason, the NCEP guidelines do not distinguish between measurements made in the laboratory or those made in alternative settings with desktop analyzers or other methods.

As mentioned previously, CDC standardization criteria consider bias and imprecision separately. For this reason, each of the two criteria must be met to achieve standardization. Current CDC standardization criteria are shown in Table 26-28.

The NCEP guidelines as summarized previously are directed primarily to laboratories and users of the laboratory measurements. The reader is referred to the original reports for more extensive discussions of these issues.[237,238] The NCEP panels have also made a number of other recommendations to improve lipid and lipoprotein measurements, only several of which are mentioned here. First, it was recommended that manufacturers of calibration materials, control pools, and analytical systems calibrate their materials and methods to provide RM equivalent values. Many manufacturers are now doing this, which probably accounts for the relatively small interlaboratory biases for total and HDL cholesterol, as reflected in Table 26-24.

Lipoprotein Separation Procedures

Several methods for separating lipoprotein fractions for subsequent analysis are included in the Evolve site that accompanies this book at http://evolve.com/Tietz/textbook.

APOLIPOPROTEINS

Apolipoproteins are measured by a wide variety of immunoassays, including radioimmunoassay (RIA), ELISA, radial immunodiffusion (RID), immunoturbidimetric assay, and immunonephelometric assay. The concentration of a particular apolipoprotein usually determines the immunotechnique used for its measurement.

Apolipoproteins A-I and B-100

Immunoturbidimetry and immunonephelometry are widely used to measure apo A-I and apo B-100, which are present at relatively high concentrations. According to the College of American Pathologists Proficiency Testing Survey, all clinical laboratories in the United States that are involved in the measurement of apo A-I and apo B-100 use one of these two approaches.[47] Alternatively, more sensitive techniques, such as ELISA and RIA, are perhaps more suitable for those apolipoproteins present at much lower concentrations, such as apo C-I and apo C-II. Additional information about the various analytical techniques used in the determination of apolipoprotein concentrations is provided later.

The following paragraphs discuss some unique analytical issues that pertain to apolipoprotein testing.[149]

Presence of a Given Apolipoprotein on Different Lipoproteins

Apolipoprotein B-100, for example, is present on LDL, IDL, VLDL, and Lp(a) particles, which vary significantly in size and composition. To determine the concentration of total apo B-100 concentration correctly, the anti–apo B-100 antibody used must be able to recognize apo B-100 present on the various lipoprotein classes equally and display similar kinetic patterns with all of them.[263]

"Masking" Phenomenon

Unlike other plasma proteins, such as transferrin and prealbumin, apolipoproteins circulate in the bloodstream as part of the lipoprotein complex. As discussed earlier, lipoprotein particles are heterogenous spheres consisting of lipids and

apolipoproteins. The antigenic sites of these proteins are often covered by lipids.[265,292] To have a maximal antigen-antibody interaction, these epitopes must be unmasked. Nonionic detergents such as Tween 20 or Tween 80 are usually added to the assay buffer to disrupt the lipoprotein particles and make all antigenic sites on the apolipoproteins accessible to the antibodies.[195,214]

Suitable Antibodies (Polyclonal Versus Monoclonal)

Polyclonal antibodies are widely used in clinical laboratories for the measurement of plasma protein concentrations. However, immunoassays are often sensitive to the nature of the antibody used.[292] The development of polyclonal antibodies is affected by several factors, such as the purity and dose of the antigen used, the species of host animal, and the immunization procedure. Monoclonal antibodies are viewed as a viable alternative to alleviate these problems. However, the expression of particular epitopes varies with the lipoprotein particles and among individuals; in addition, the apolipoproteins themselves are polymorphic in nature. Therefore the use of a single monoclonal antibody might not detect a particular variant. If a monoclonal antibody is used in the determination of an apolipoprotein, it should be directed to an epitope that is expressed on all polymorphic forms of that particular apoprotein. Furthermore, the epitope should be equally reactive to the antibodies regardless of which lipoprotein class contains it. Alternatively a mixture of monoclonal antibodies directed at different epitopes of the apolipoprotein may also be used. Such mixtures are referred to as "panmonoclonal" antibodies.

Availability of Primary Calibrators

In general, to standardize a particular protein, a purified form of that protein is used as a primary calibrator (see Chapter 20). The purified preparation must, however, express the same immunoreactivity as the native protein. Unfortunately, once removed from its natural milieu, apo B-100 is insoluble in aqueous buffers.[161] This phenomenon is attributed to the very hydrophobic nature of apo B-100. An LDL preparation with density of 1.030 to 1.050 g/mL, often referred to as "narrow-cut" LDL, is generally used as the primary standard for apo B-100. The protein concentration of the purified preparation is determined by amino acid analysis. In contrast, freshly purified apo A-I is soluble in aqueous buffers and is suitable as a primary standard.

As indicated earlier, several immunotechniques are used for the quantification of apo A-I and apo B-100. These techniques are affected differently by the analytical issues discussed previously. RIA and ELISA, for example, are normally used for the determination of analytes present at these very low concentrations (nanograms per milliliter). Therefore large dilutions (up to 40,000-fold) are required when these techniques are applied to apo A-I or apo B-100 measurement, which can result in a substantial analytical error. In addition, these assays are relatively time consuming and not easily automated, and RIA requires the use of isotopes. However, these techniques permit the use of monoclonal or polyclonal antibodies and primary or secondary calibrators, and are less affected by the matrix of the specimen, thus permitting the determination of protein concentration in the presence of lipemia. RID is a slow technique. For example, it takes up to 3 days for VLDL to complete migration through the gel. It is also less precise than automated assays and yields lower apo B-100 values than those obtained by other techniques,[57,263] possibly in part because of the relative selectivity of RID for smaller apo B–containing particles. Either polyclonal or monoclonal antisera may be used with RID.[149] Immunoturbidimetric and immunonephelometric assays are fully automated, highly precise, and can use polyclonal or multiple monoclonal antibodies. However, they can be affected by the background turbidity of the specimen (e.g., in samples with high triglyceride concentrations). The addition of detergents to the assay buffers reduces the nonspecific light scattering, which has helped to diminish this problem.

Considerable effort has been expended over the past decade by national and international organizations in overcoming the problems of apo A-I and B-100 standardization.[57] The lack of internationally available secondary serum reference materials had been a major stumbling block in the standardization of these apolipoproteins. The Committee on Apolipoproteins of the IFCC embarked on an ambitious international collaborative study aimed at developing secondary serum reference materials that can be used, without fear of matrix interaction, as master calibrators for all current commercial assays.[171] This program has been successfully completed.[174,175] A lyophilized serum preparation for apo A-I, designated SP1-01, and a liquid-stabilized serum preparation for apo B-100, designated SP3-07, have been approved as international reference reagents by the World Health Organization (WHO). An apo A-I value of 150 mg/dL was assigned to SP1-01 by a highly standardized RIA calibrated with purified apo A-I for which the mass value had been determined by amino acid analysis.[174] An accuracy-based apo B-100 value of 122 mg/dL was assigned to SP3-07 using a nephelometric method that was calibrated with freshly isolated LDL for which the apo B-100 mass value was determined by a standardized sodium dodecyl sulfate–Lowry protein procedure.[175]

The WHO and the IFCC have appointed the CDC to be the repository for the WHO-IFCC First International Reference Reagents for Apolipoproteins A-I and B-100. Dr. Santica Marcovina of Northwest Lipid Research Laboratories (NWLRL) in Seattle, who is the former Chair of the IFCC Apolipoprotein Working Group, conducts the standardization and distribution program for manufacturers of instruments and reagents using an IFCC calibration protocol. This protocol involves establishing the linearity of dose response, the parallelism of the kinetic responses of standards and calibration sera, and the equality of the intercepts for the reference materials and an analysis of fresh-frozen sera. NWLRL can be contacted for standardization

services and the distribution of apolipoprotein reference materials. These reference reagents are also available for reference laboratories in countries where standardized commercial methods are not readily available. It has been shown that through the use of these international reference materials, the analytical performance of apo A-I and apo B-100 measurement, in terms of accuracy and precision, is superior to that of HDL and LDL cholesterol.[174,175] This effort has demonstrated that the use of certified reference materials can significantly reduce the bias of apo A-I and apo B-100 measurements by different immunotechniques. However, an external quality assurance program using fresh or fresh-frozen samples and WHO-IFCC–based value assignments is indispensable in monitoring the performance of clinical chemistry laboratories and manufacturers to ensure that accurate apolipoprotein measurements are made. The NWLRL conducts a quarterly standardization program or Reference Lipoprotein Analysis Basic Survey that provides the accuracy base for cholesterol, triglyceride, HDL, and LDL cholesterol, and apo A-I and apo B-100. To minimize matrix effects, the survey uses fresh human serum and leads to certification of traceability to the National Reference System for cholesterol and to the WHO-IFCC International Reference Reagents for apo A-I and apo B-100.

Apolipoprotein measurements have been shown to further aid in the detection of the CHD risk and the diagnosis of hyperlipoproteinemia. For example, the measurement of apo B-100 provides a reliable clinical tool to identify subjects with an increased risk for CHD who may not be readily identified by the conventional cholesterol or lipoprotein cholesterol measurements (e.g., subjects with a borderline elevation of LDL cholesterol, or subjects with hypertriglyceridemia without an LDL cholesterol elevation). In addition, apo B-100 measurements can assess whether lipid-lowering drugs are effective in lowering the number of atherogenic apo B–containing lipoproteins. However, for apolipoprotein measurements to be used in routine clinical practice, clinically meaningful cut-off values for clinical decision making need to be established, and more information regarding their clinical utility is needed. The use of cut-off values for apo A-I and apo B-100 similar to those recommended by the NCEP for HDL and LDL cholesterol, respectively, has been suggested.[54,55] An apo A-I concentration of <120 mg/dL may be associated with an increased risk of CHD, whereas apo A-I ≥160 mg/dL may be protective. The apo B-100 cut points of 100 and 120 mg/dL approximately correspond to the LDL cholesterol cut points of 130 and 160 mg/dL, which fall at approximately the 50th and 75th percentiles, respectively. Therefore Sniderman and Cianflone have suggested that apo B-100 values greater than the 75th percentile should be regarded as high risk, and a value greater than the 50th percentile as moderate risk.[284]

Lipoprotein(a)

The structural heterogeneity of Lp(a) as a consequence of the apo(a) size heterogeneity has important implications for the accurate measurement of Lp(a) in human plasma.[10,172,173,179,180] Repeated antigenic determinants are present in variable numbers in different Lp(a) particles, and the immunoreactivity of the antibodies directed to these repeated epitopes can vary as a function of apo(a) size. As a consequence, immunoassays using polyclonal antibodies or monoclonal antibodies specifically directed to kringle 4 type 2 epitopes will tend to underestimate apo(a) concentration in samples with apo(a) of smaller size than the apo(a) present in the assay calibrator, and overestimate the apo(a) concentration in samples with larger apo(a). A detailed evaluation of the effect of apo(a) size heterogeneity on the measurement of Lp(a) has been reported.[173] Monoclonal antibody–based assays have the theoretical advantage that the antibodies can be immunochemically characterized and preselected on the basis of their specificity to single epitopes (e.g., those not located in kringle 4 type 2 domain). However, the characterization of monoclonal antibodies is a rather complex procedure, and none of the monoclonal antibodies currently used in commercially available assays has been characterized in terms of epitope specificity. An additional disadvantage of monoclonal antibodies is that they cannot be easily used in immunoassays that require the precipitation of the antigen-antibody complex.

Turbidimetric, nephelometric, radiometric, and enzymatic methods are currently used for Lp(a) measurement. Most of these assays, except the enzyme immunoassays (ELISA), are based on the use of polyclonal antibodies from various animal species. Commercially available, direct-binding, sandwich type ELISAs are usually based on the use of a combination of monoclonal and polyclonal antibodies. One approach takes advantage of the presence of both apo(a) and apo B in Lp(a) particles. In this approach, Lp(a) particles are "captured" using a polyclonal or monoclonal antibody to apo(a), and an enzyme-conjugated antibody to apo B-100 used as the detection antibody. An ELISA method based on this approach has been described and is commercially available.[298] In another approach, both the capture and detection antibodies are specific for apo(a). At present, it is not clear which approach would be better with respect to estimating the risk for CHD or stroke because the pathogenic mechanisms involved have not yet been elucidated. Thus it is not known whether the risk is associated simply with an increased number of Lp(a) particles in the circulation (as measured using an anti–apo B antibody) or also related to the presence of particular size polyforms [as might be detected more readily with anti-apo(a) detection antibodies]. It is likely that both factors influence the risk.

Historically, Lp(a) concentrations have been reported in terms of total Lp(a) particle mass,[3] or alternatively in terms of Lp(a) protein.[172] If the aim is to provide Lp(a) values that are independent of apo(a) size, it is recommended that the Lp(a) assay use antibodies directed to an apo(a) domain other than kringle 4 type 2, or to the apo B-100 component of Lp(a). This would allow the values to be expressed in

nanomoles per liter.[4] Panmonoclonal mixtures of antibodies to kringle 4 type 2 may be preferred if particular sizes of polyforms contribute to the risk.

At present, Lp(a) measurements are not standardized, and most of the Lp(a) assays have not been evaluated for their apo(a) size sensitivity. As a result, Lp(a) values reported in clinical studies are difficult to compare. Despite this, a value of about 30 mg/dL of total Lp(a) particle mass has traditionally been used as a cutoff above which elevated levels of Lp(a) are associated with an increased risk of CHD. Lp(a) concentrations can also be expressed in terms of particle number, the mass of apo(a), apo B-100, or Lp(a) cholesterol. Which approach will best predict the risk for CHD has yet to be determined. At present, Lp(a) values are most commonly expressed in terms of total Lp(a) mass, but this should be confirmed with the laboratory making the measurements. In view of the current lack of RMs or standardization procedures for Lp(a), it is difficult to define precise cutoffs that can be used to make clinical decisions. Although less than ideal, one approach would be to establish a reference interval for each assay, and report individual results in terms of percentile values within these intervals. In whites, patients with Lp(a) values above the 80th percentile can be considered at an increased risk for coronary atherosclerosis. However, because Lp(a) values can vary among ethnic groups, reference values need to be population based. Furthermore, such cutoffs may also have to be racially specific. For example, African Americans in general have significantly higher Lp(a) concentrations than whites,[181] but do not manifest a higher incidence of CHD. An IFCC committee, along lines similar to the apo A-I and B-100 committee, has developed reference materials to be used with all commercially available Lp(a) methods.[300,301] As expected, the use of a common calibrator led to harmonization of Lp(a) results but not total standardization.[176] Only when appropriate antibodies are used can standardization be achieved.

Virtually all retrospective case-control studies in whites have reported a strong association between increased Lp(a) and the risk of CHD. In contrast, prospective studies have provided contradictory results, with four of them finding an association between high Lp(a) concentrations and CHD and three not finding any association. Interestingly, the few clinical studies in which Lp(a) was evaluated as a CHD risk factor in African Americans suggest that elevated Lp(a) is not as important a risk factor in this group.

Several studies have suggested that apo(a) size isoforms may be related to a high prevalence of CHD (see earlier discussion). The procedure with the highest resolution and sensitivity for determination of apo(a) phenotypes involves separation of apo(a) on agarose gel electrophoresis, immunoblotting with a specific antibody, and detection with ^{125}I-labeled protein A.[181] This approach identifies at least 34 apo(a) polymorphs. It can be used to express apo(a) size in terms of kringle number, and is consistent with observations on the size variation of the apo(a) gene obtained by pulsed-field gel electrophoresis and genomic blotting.[178]

APOLIPOPROTEIN E

As discussed earlier, homozygosity for apo E_2 is characteristic of type III familial hyperlipoproteinemia. Homozygosity for apo E_2 is a necessary but not sufficient condition for expression of the type III hyperlipoproteinemia; a second gene defect or condition appears to be required to cause the characteristic hyperlipidemia. Heterozygosity for some rare apo E mutants may also be associated with type III hyperlipoproteinemia.[311] The study of apo E variants has assumed greater importance in the last few years because of the association between the apo E_4 allele and Alzheimer's disease and dementia.[279] How apo E_4 is related to these disorders is unknown.

Traditionally the determination of apo E isoforms was assessed by isoelectric focusing (IEF) techniques that permit identification of charge variations of the different isoforms. In the early studies, IEF was performed on VLDL that had been extracted to remove the lipids. The separated proteins were then stained for protein.[325] This approach is not used as frequently today because it requires a relatively large volume of plasma and the expensive and time-consuming step of ultracentrifugation to isolate VLDL. Apo E phenotypes are now assessed by IEF of a small volume of plasma followed by immunoblotting with specific antibodies to apo E. This approach can be applied in the clinical laboratory and is well adapted to large-scale population studies. However, it is important that the samples are analyzed fresh, or if stored, that they are kept at −70 °C before analysis to minimize the introduction of artifacts. Misclassification can occur because of posttranslational modifications or nonenzymatic glycation of apo E, the presence of rare variants that have the same charge as the common isoforms, overlooked faint apo E_4 bands, and false-positive apo E_2 bands. The interpretation of the patterns requires significant experience in the use of the technique.

The availability of techniques based on the polymerase chain reaction (PCR) permits an analysis of the variation in the nucleotide sequence of the apo E gene (Figure 26-27). One approach for apo E genotyping uses oligonucleotides to amplify apo E gene sequences containing amino acid positions 112 and 158; the amplified products are digested with *Hha*I and subjected to electrophoresis on polyacrylamide gels.[112] Alternatively, allele-specific oligonucleotide (ASO) primers can be used to specifically amplify E_2, E_3, and E_4 polymorphic sequences of the apo E gene.[99,330] Another approach, the amplification refractory mutation system (ARMS), is based on the strictness of the PCR primer for the 3′ end mismatch and is simple, rapid, and nonisotopic. The reagent costs for the ARMS assay are, however, higher than for the restriction isotyping assay. The single-strand conformation polymorphism (SSCP) method has also been used for apo E genotyping.[73] It can detect unknown apo E mutations but is not very convenient because it requires radiolabeled primers. Because restriction isotyping is rapid, requiring only 1 hour to digest the PCR product and several hours for electrophoresis, and does not require radioactive

reagents, it may be the most practical method for apo E genotyping in the diagnostic clinical laboratory. Good-quality deoxyribonucleic acid (DNA) ensures proper amplification and prevents the presence of artifactual bands. Because of potential errors in interpretation or unpreventable artifacts in the apo E phenotype method, apo E genotyping is more reliable for determining the common apo E alleles and would be the method of choice if DNA or whole blood is available. However, most apo E genotyping methods do not detect rare mutations. Discrepancies of 5% to 20% between the results of phenotyping and genotyping have been reported.

OTHER CARDIAC RISK FACTORS

Despite the strong association of lipid concentrations with a CHD risk, it has been long recognized that half of all myocardial infarctions occur among individuals without overt hyperlipidemia. In the Women's Health Study (WHS), for example, 77% of future cardiovascular events occurred among those with LDL cholesterol concentrations <160 mg/dL, and 46% occurred among those with LDL cholesterol <130 mg/dL.[253] Furthermore, in a 2003 study analysis of more than 120,000 patients, approximately 20% of all coronary events occurred in the absence of any of the major classical risk factors: hyperlipidemia, hypertension, diabetes, and smoking.[133] Another large study showed that 85% to 95% of participants with CHD had at least one conventional risk factor, but so too did those participants without CHD, despite follow-up for as long as 30 years.[100] These observations raise the question whether only traditional risk factors are adequate to identify all individuals at an increased risk of CHD.

A wide variety of nonlipid biochemical markers have been suggested in an effort to better identify those individuals at an increased CHD risk, including markers of fibrinolytic and hemostatic function (tissue type plasminogen activator antigen, plasminogen activator inhibitor-1, fibrinogen, von Willebrand, D-dimer, thrombin-antithrombin III complex, and factors V, VII, and VIII), homocysteine, and markers of inflammation (high-sensitivity C-reactive protein (hsCRP), serum amyloid A, interleukins, adhesion molecules, heat shock proteins, and matrix metalloproteases). Clinically the use of most of these markers in screening is of limited value for one or more of the following reasons:

1. Lack of standardization among available methods (e.g., fibrinogen)
2. Inconsistent findings from prospective epidemiological studies regarding their ability to independently predict a future CHD risk (see discussion on homocysteine later in this chapter)
3. Inability to significantly improve prognostic value when added to traditional lipid screening or existing global risk prediction algorithms, such as the Framingham risk score (e.g., tissue type plasminogen activator)

In this section, hsCRP and homocysteine are discussed in more detail.

HIGH-SENSITIVITY C-REACTIVE PROTEIN

Tillet and Francis in 1930 described a substance that was present in the sera of acutely ill patients and able to bind the cell wall C-polysaccharide of *Streptococcus pneumoniae* and agglutinate the organisms. In 1941 the substance was shown to be a protein and given the name *C-reactive protein (CRP).*

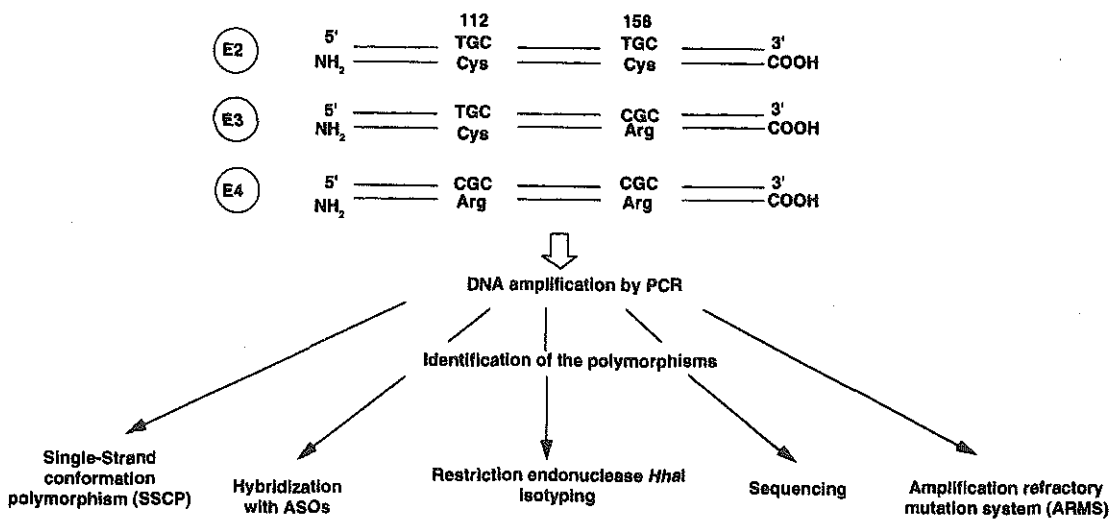

Figure 26-27 Different methods for investigating apolipoprotein E polymorphism at the genomic level. *PCR,* polymerase chain reaction; *ASO,* allele-specific oligonucleotide. *(From Siest G, Pillot T, Regis-Bailly A, et al. Apolipoprotein E: An important gene and protein to follow in laboratory medicine. Clin Chem 1995;41:1068-86.)*

CRP was subsequently shown to be an acute phase reactant and important in the nonspecific host defense against inflammation, especially infection (see Chapter 20) and is routinely monitored as an indication of infection and autoimmune diseases using methods having detector limits of 3 to 8 mg/L.

Chronic inflammation is an important component in the development and progression of atherosclerosis, and numerous epidemiological studies have demonstrated that increased serum CRP concentrations are positively associated with a risk of future coronary events, such as coronary artery disease, cerebrovascular disease, or peripheral arterial disease.[140,247-249] It has also been shown to be predictive of future events in patients with acute coronary syndromes and in patients with stable angina and coronary artery stents.[264]

The use of CRP for these purposes requires the use of hsCPR assays having detection limits less than 0.3 mg/L.[264] A number of automated immunoturbidimetric and immunonephelometric assays are commercially available and capable of sensitive and precise measurements at low concentrations of CRP. The analytical performance of nine of these assays has been evaluated.[264]

In this section, we summarize the basic biochemistry, clinical significance, and analytical considerations of the measurement of hsCRP. Additional information is presented in Chapter 20.

Biochemistry

CRP consists of five identical, nonglycosylated polypeptide subunits noncovalently linked to form a disk-shaped cyclic polymer with a molecular weight of ~115 kDa. It contains little or no carbohydrate and is synthesized in the liver. Its production is controlled by interleukin-6 and it binds to polysaccharides present in many bacteria, fungi, and protozoal parasites and polycations, such as histones.

Clinical Significance

Of the markers mentioned previously in this chapter, only hsCRP has fulfilled the required criteria for a novel marker of CHD risk, and national guidelines for its measurement in the primary prevention of CHD have recently been issued jointly by the American Heart Association (AHA) and the CDC (AHA/CDC).[226] Here we discuss the roles of hsCPR in CHD, the metabolic syndrome, diabetes, and hypertension, and its possible role in atherogenesis. We conclude with a discussion of possible preventive measures in those individuals with increased levels of hsCRP. A comprehensive review on this subject has been published.[23]

Cardiovascular Disease

Prospective epidemiological studies have consistently shown that a single hsCRP measurement is a strong predictor of myocardial infarction,[140,146,249,253] stroke,[146,249,253] peripheral vascular disease,[248,254] and sudden cardiac death[5] in individuals without a history of heart disease. The association between hsCRP and future CHD reflects the current understanding of vascular biology because it is known that chronic inflammation plays a pivotal role in atherogenesis. This association has been observed in the United States and Europe, in the middle aged and elderly, and in high- and usual-risk populations.[5,140,146] The association is apparent even in studies with follow-up periods up to 20 years, as seen in the Honolulu Heart Study.[60] In a direct comparison of traditional and novel biochemical markers of CHD risk, hsCRP was the strongest predictor of future coronary events.[249]

In general, those individuals with baseline hsCRP values in the top quartile of the sample distribution are 2 to 3 times more likely to experience a future vascular event than those in the bottom quartile. The association between hsCRP and future vascular events is linear and is independent of age, smoking, hypertension, dyslipidemia, and diabetes. For example, 8-year follow-up data from the Physicians' Health Study and the WHS showed that after adjustment for traditional risk factors, there was an increase in a future cardiovascular risk of 26% for men and 33% in women for each quintile increase in baseline hsCRP.[249]

Although most of the available data on hsCRP and incident CHD have been derived from nested case-control studies, event-free survival data from large cohorts have been published[250,253] thus enabling the estimation of absolute risks rather than relative risks of disease. Data from the WHS showed hsCRP to be a stronger predictor of the risk than LDL cholesterol (Figure 26-28) and demonstrated that event-free survival was poorest for persons with increases in both LDL cholesterol and hsCRP, and the best survival was observed for those with low values of both measures.[253] Event-free survival was significantly worse for those with high hsCRP and low LDL cholesterol as compared with those with high LDL cholesterol and low hsCRP (Figure 26-29).

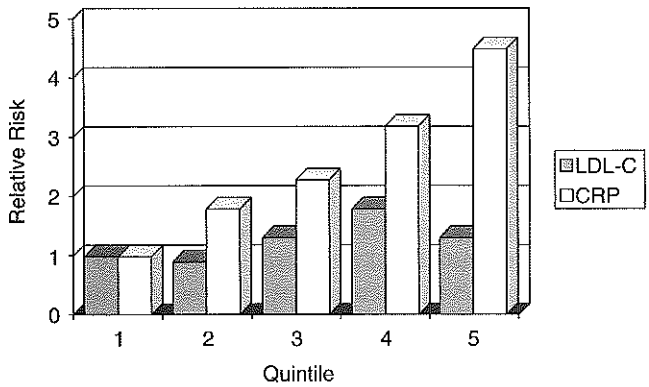

Figure 26-28 Head-to-head comparison of LDL cholesterol and hsCRP in their ability to predict future vascular events. *LDL*, Low-density lipoprotein cholesterol; *hsCRP*, high-sensitivity C-reactive protein. *(From Ridker PM, Rifai N, Rose L, Buring JE, Cook NR. Comparison of C-reactive protein and low-density lipoprotein cholesterol levels in the prediction of first cardiovascular events. N Engl J Med 2002;347:1557-65.)*

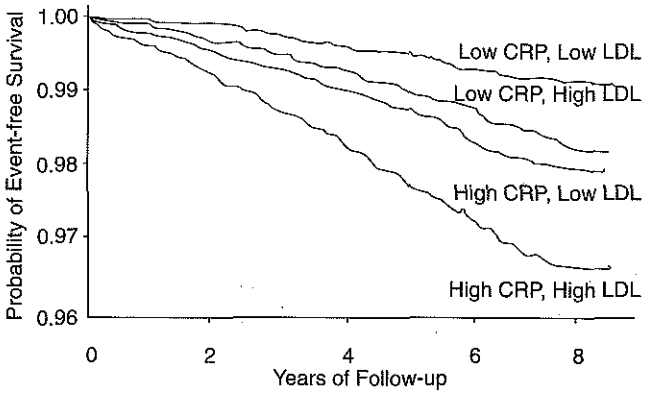

Figure 26-29 Cardiovascular event-free survival according to baseline levels of hsCRP and LDL cholesterol. *(From Ridker PM, Rifai N, Rose L, Buring JE, Cook NR. Comparison of C-reactive protein and low-density lipoprotein cholesterol levels in the prediction of first cardiovascular events. N Engl J Med 2002;347:1557-65.)*

Since hsCRP values minimally correlate with lipid concentrations and lipid parameters account for <3% to 5% of the variance in hsCRP measurement, the measurement of hsCRP does not replace but instead complements the evaluation of lipids and other classical CHD risk factors in primary prevention settings.[6,250,253] Data from the WHS demonstrated that hsCRP adds prognostic information not only at all levels of the risk defined by current LDL cut points of the NCEP but also at all levels of the risk specified by the Framingham risk score algorithm.[253]

Metabolic Syndrome, Diabetes, and Hypertension

Studies have demonstrated a significant association between hsCRP and the future risk of metabolic syndrome,[285] diabetes, and hypertension, conditions that confer an increased cardiovascular risk. The hsCRP values are positively correlated not only with components of the metabolic syndrome that are commonly assessed in clinical practice, such as increased triglycerides, reduced HDL cholesterol, obesity, high blood pressure, and high fasting glucose, but also with other components that are not easily captured in such settings, such as fasting insulin, microalbuminuria, and impaired fibrinolysis.[232] Data from the WHS showed that hsCRP measurement improves the cardiovascular risk prediction beyond that of the metabolic syndrome status as assessed in clinical practice[246]; those women with metabolic syndrome and hsCRP >3 mg/L were at twice the risk of future coronary events compared with those with metabolic syndrome and hsCRP <3 mg/L. Similar results were observed in the West of Scotland Coronary Prevention Study (WOSCOPS).[268]

Increased hsCRP concentrations have also been implicated in the development of type 2 diabetes mellitus. Prospective studies have found strong, graded relationships between hsCRP and incident diabetes, which in many instances persisted after adjustment for body mass index and other covariates.[233] In WOSCOPS, the top quintile of hsCRP was associated with a threefold risk of incident diabetes over a 5-year period compared with the lowest quintile[82] and in the WHS, the top quartile of hsCRP was associated with a fourfold risk during 4 years of follow-up compared with the lowest quartile.[233] These data support the hypothesis that inflammation, atherothrombosis, and diabetes are tightly interrelated disorders of the innate immune system.

Accumulating data also suggest a link between blood pressure and vascular inflammation, perhaps mediated by angiotensin II.[161] For example, angiotensin II infusion activates nuclear factor κB and leads to increased interleukin-6 expression in human vascular smooth muscle cells.[143] Moreover, cross-sectional studies demonstrate graded linear relationships between interleukin-6 and intercellular adhesion molecule-1 and both systolic and diastolic blood pressure.[43] The relationship between blood pressure, hsCRP, and incident cardiovascular events was assessed in the WHS.[25] Despite their strong correlation, hsCRP and blood pressure were independent determinants of future cardiovascular events during an 8-year follow-up period, and hsCRP retained incremental prognostic value at all levels of blood pressure. Compared with women with blood pressures of less than 120/75 mm Hg and hsCRP values of <3 mg/L, those with blood pressures of 160/95 mm Hg and hsCRP values of ≥3 mg/L were more than 8 times as likely to experience a future cardiovascular event. The hsCRP also predicts incident hypertension itself. In the same cohort, after adjustment for multiple potential confounders, those women in the highest quintile of hsCRP were at a 50% higher risk of developing hypertension compared with those in the lowest quintile.[277] Moreover, high hsCRP concentration was associated with an increased risk of incident hypertension at all baseline blood pressures and among individuals without traditional CHD risk factors. On the basis of these data, it has been hypothesized that hsCRP may play a critical role in the development of hypertension. Whether or not blood pressure reduction leads to reduced hsCRP values is uncertain and is being tested in an ongoing clinical trial.

Possible Role of CRP in Atherogenesis

It is not clear at present whether CRP is a marker that reflects systemic or vascular inflammation or is an actual participant in atherogenesis. However, findings from pathological and in vitro studies are increasingly supporting the latter. Recent reports have shown CRP to enhance expression of local endothelial cell surface adhesion molecules,[223] monocyte chemoattractant protein-1,[223] endothelin-1,[314] and endothelial plasminogen activator inhibitor-1[69]; reduce endothelial nitric oxide bioactivity[314]; increase the induction of tissue factor in monocytes[202] and LDL uptake by macrophages[338]; and co-localize with the complement membrane attack complex within atherosclerotic lesions.[304] In addition, it has been demonstrated that the expression of human CRP in CRP-transgenic mice directly enhances intravascular thrombosis in both arterial injury and photochemical injury models of endothelial disruption.[304]

Role in Disease Intervention

Although many behavioral and pharmacological interventions known to reduce the risk of clinical cardiovascular events have been linked to lower hsCRP values, it is not definitely known at present whether the lowering of hsCRP will necessarily lead to a reduction in vascular events. For example, a reduction not only in hsCRP but also in several proinflammatory cytokines and adhesion molecules was seen in obese premenopausal women assigned to a weight-loss program as compared with women in the control group.[336] Whether these effects translate into a reduced risk of subsequent cardiovascular events has not yet been elucidated.

Although no specific drugs are known to lower hsCRP concentrations, several pharmacological agents have demonstrated cardioprotective ability, such as aspirin and statins, with the latter being able to reduce hsCRP values. In the Physicians' Health Study, a large primary prevention trial, the reduction in the risk of future myocardial infarction associated with assignment to aspirin was 56% among those with baseline hsCRP concentrations in the highest quartile and declined proportionately with hsCRP values such that there was a reduction of only 14% among those in the lowest quartile, suggesting that aspirin may prevent ischemic events through antiinflammatory and antiplatelet effects.[247] The effect of aspirin on lowering hsCRP concentrations is uncertain at present.

The ability of statins to lower hsCRP was first described for pravastatin using data accumulated in the Cholesterol and Recurrent Events (CARE) trial.[251,252] These data were initially highly controversial because they suggested that statins have both lipid-lowering and antiinflammatory effects. However, confirmatory work rapidly showed the effect of statins on hsCRP to be a consistent and important class effect. Studies of atorvastatin, cerivastatin, lovastatin, pravastatin, and simvastatin have shown that, on average, median hsCRP concentrations decline 15% to 25% as early as 6 weeks after initiation of therapy.[21] Importantly the magnitude of LDL cholesterol reduction caused by statin therapy is minimally correlated with the magnitude of hsCRP reduction.[21]

Data from two large 5-year randomized trials suggest that the cardiovascular risk reduction attributable to statin therapy may be most marked for those with increased hsCRP concentrations at baseline. In the CARE trial, the proportion of recurrent events prevented by pravastatin was 54% among persons with increased hsCRP values but only 25% among persons with lower hsCRP values, even though baseline lipid concentrations were nearly identical in those with and without evidence of inflammation.[252] Similarly, in the Texas Air Force Coronary Atherosclerosis Prevention Study, lovastatin therapy was associated with a 42% reduction in first cardiovascular events among participants with low LDL cholesterol concentrations (<149 mg/dL) but high hsCRP values (>1.6 mg/L).[250] As a result of these provocative findings, JUPITER—a clinical trial specifically designed to test the efficacy of statins in reducing clinical cardiovascular events among persons with the high hsCRP/low LDL phenotype, who comprise an estimated 25% of the U.S. population—has recently been launched.

Analytical Considerations

As discussed in Chapter 20, historically, CRP has been measured in clinical laboratories to monitor active infection. Although such assays are automated and reproducible, they have a lower detection limit of 3 to 8 mg/L and thus are not sensitive enough to detect the low-end variations required for prediction of the vascular risk. Therefore high-sensitivity methods had to be developed for this clinical application. Of various techniques used by investigators and manufacturers to improve the sensitivity of CRP assays, the most successful approach has been to amplify the light-scattering properties of the antigen-antibody complex by covalently coupling latex particles to a specific antibody, a procedure that is easily automated using standard laboratory instrumentation. More than 30 types of hsCRP assays, most of which use this approach, are now commercially available.[158] In a study of nine such assays, all achieved a lowest detection limit of ≤0.3 mg/L, and five had within-laboratory analytical imprecision of <10% (i.e., reproducibilities >90%).[264] However, hsCRP assays from different laboratories show significant discrepancies in reported results, underscoring the need for additional standardization.[264]

Standardization

Agreement among hsCRP methodologies is essential because an individual patient's result will be interpreted within the context of nationally established cut points. A standardization program led by the CDC has been initiated to address this issue.[136] Phase I, which has been completed, had identified a suitable common calibrator. The European Community Bureau of Reference Certified Reference Material 470 (CRM 470) Phase II, which is ongoing, will verify whether the use of this standard leads to a harmonization of patients' results.

Biological Variability of CRP

Despite being an acute phase reactant, hsCRP exhibits a relatively low degree of intraindividual variability in clinically stable patients. In a study of such patients, the use of two independent measurements of hsCRP taken 90 days apart enabled the classification of 90% of participants into the exact or immediately adjacent biomarker tertile, a percentage comparable with that observed for cholesterol (Figure 26-30).[158,217] Furthermore, the age-adjusted correlation between two hsCRP measurements from blood samples drawn 5 years apart was 0.6, a value comparable with that of cholesterol and other lipid parameters.[251] Other groups of investigators reported a 3-year, age-adjusted reliability coefficient of 0.52.[141] Although findings from this epidemiological study of initially healthy middle-aged men suggest that three independent measurements be taken to maximize the

biomarker's predictive ability,[141] whether serial assessment of hsCRP provides incremental clinical benefit is uncertain. Provided that a value of <10 mg/L is obtained, the AHA/CDC panel recommends the use of two hsCRP measures taken 2 or more weeks apart, with the average value used to estimate the vascular risk.[226] Since they may reflect subclinical infection, hsCRP values >10 mg/L should initially be disregarded and the test repeated when the patient has stabilized. Furthermore, since hsCRP values are unaffected by food intake and exhibit almost no circadian variation,[188,217] measurements can be made without regard for fasting status or time of day.

Preanalytic and analytic sources of variations in C-reactive protein measurement: implications for cardiovascular disease risk assessment. Clin Chem 2003;49:1258-71.)*

Reference Values

Data from several large U.S. and European cohorts indicate that the distribution of circulating hsCRP concentrations appears comparable among men and women not using postmenopausal hormone replacement therapy (HRT),[120,262] with the 50th percentile for both genders being about 1.5 mg/L (Table 26-29). hsCRP concentrations are higher in women who use oral HRT than in women who do not,[253] which suggests that the increased hsCRP may be at least partly responsible for the increased risk of thrombotic events associated with oral HRT use observed in randomized trials, such as the WHS.[170]

Information on the distribution of hsCRP concentrations in nonwhite populations is sparse. In the nationally representative NHANES dataset, there were no significant differences in the distributions of hsCRP concentrations among white, African-American, and Mexican-American men[79] (Table 26-30). Moreover, a comparable hsCRP distribution was seen in Japanese men.[333] Although additional studies on

Clin Chem 2003;49:686-90; Yamada S, Gotoh T, et al. Distribution of serum C-reactive protein and its association with atherosclerotic risk factors in a Japanese population: Jichi Medical School Cohort Study. Am J Epidemiol 2001;153:1183-90.

the distribution and prognostic ability of CRP in nonwhite populations are clearly necessary, existing data is insufficient to support the exclusion of any racial or ethnic group from current guidelines for CRP testing.

Most studies have reported only a modest relationship between age (range, 18 to 88 years) and serum hsCRP concentrations.[120,262] In the WHS, for example, median hsCRP concentrations for individuals aged 45 to 54, 55 to 64, 65 to 74, and 75 years or older were 1.31, 1.89, 1.99, and 1.52 mg/L, respectively.[262]

Reference values of less than 1, 1 to 3, and greater than 3 mg/L, which correspond to approximate tertiles of the CRP distribution in healthy adults, are recommended for classification of individuals into low-, moderate-, and high-cardiovascular risk groups in primary prevention settings by the AHA/CDC panel.[226] Because of the prognostic additive effect of hsCRP to the lipid screen, an algorithm combining hsCRP and LDL cholesterol using the NCEP cut points has been proposed (Figure 26-31).[262] According to the AHA/CDC recommendation, hsCRP should be part of the global risk assessment of CHD in the primary prevention setting, and individuals with moderate risk as determined by the Framingham risk score will benefit the most from its measurement.[226]

HOMOCYSTEINE

Many disorders are associated with increased levels of total homocysteine.[241] In this section, the basic biochemistry, clinical significance, and measurement of total homocysteine (tHcy) are summarized.

Basic Biochemistry

Homocysteine is a sulfur-containing amino acid with each molecule of homocysteine containing one atom of sulfur. It is formed during the metabolism of methionine and requires folic acid as a cofactor (see Figure 26-32). At low concentrations, homocysteine is either anabolized back to methionine in a cycle that involves tetrahydrofolate or catabolized to cysteine by enzymes that require vitamin B as a cofactor. Consequently a deficiency of folic acid or vitamins B_6 and B_{12} can result in increased levels of homocysteine (see Chapter 30).[138,269] Homocysteine does not normally accumulate in plasma because it is very unstable in aqueous solution and, when present in excess, undergoes oxidation to homocystine.

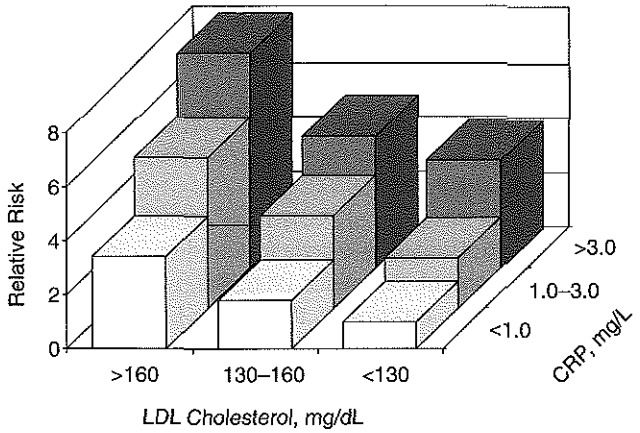

Figure 26-31 Algorithm for risk assessment of CHD risk employing CRP and LDL cholesterol. *(From Rifai N, Ridker PM. Population distributions of C-reactive protein in apparently healthy men and women in the United States: implication for clinical interpretation. Clin Chem 2003;49:666-9.)*

Clinical Significance

Numerous studies have suggested an association between elevated levels of circulating homocysteine and various vascular and cardiovascular disorders.* In addition, tHcy levels also are related to birth defects,[236] pregnancy complications,[318] psychiatric disorders,[213] and mental impairment in the elderly.[281] Clinically the measurement of tHcy is considered important (1) to diagnose homocystinuria, (2) to identify individuals with or at a risk of developing

*References 29, 66, 116, 193, 216, 228, 242.

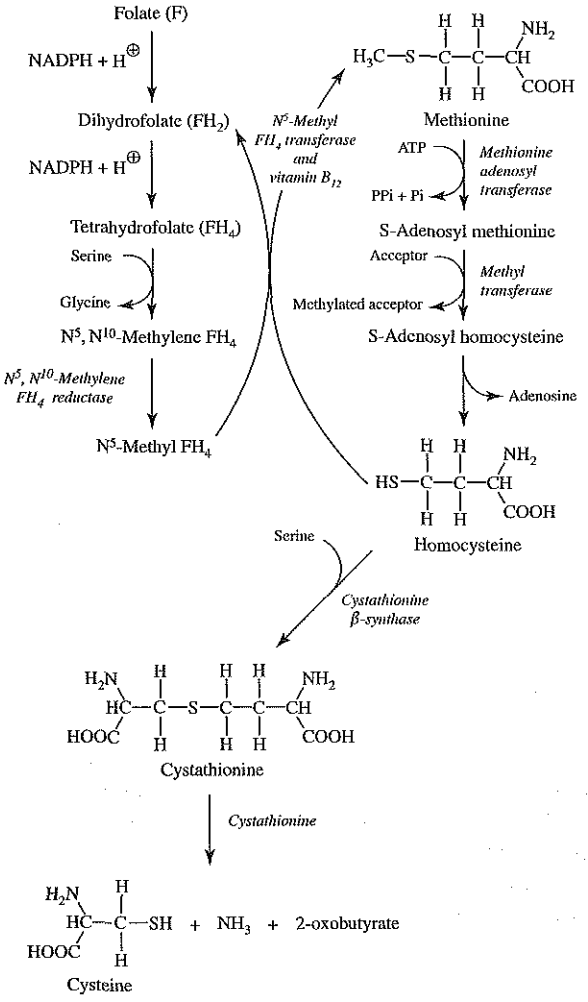

Figure 26-32 Biochemical pathways of the conversion of methionine to homocysteine and cysteine.

cobalamin or folate deficiency, and (3) to assess tHcy as a risk factor for cardiovascular disease (CVD) and other disorders.[40,46,241,320]

Although numerous studies have demonstrated a causal relationship between tHcy and CVD, there is still controversy about the clinical significance of this relationship as (1) the MTHFR 677C→T polymorphism is a strong risk factor for increased tHcy but not for CVD; (2) there is an apparent discrepancy between prospective and retrospective case-control studies; and (3) there is a lack of data from controlled clinical trials.[241]

Because of this concern over the clinical significance of the causal relationship between tHcy and CVD[28,152,168,239,288] Refsum and colleagues developed the following recommendations[241]:

- Measurement of tHcy in the general population to screen for CVD risk is not recommended.
- In young CVD patients (<40 years), tHcy should be measured to exclude homocystinuria.
- In patients with CVD or persons with a high risk of CVD events, a high tHcy concentration should be used as a prognostic factor for CVD events and mortality.
- CVD patients with tHcy >15 µmol/L belong to a high-risk group; it is especially important for them to follow a healthy life-style and to receive optimal treatments for known causal risk factors.
- Increased tHcy combined with low vitamin concentrations should be handled as a potential vitamin deficiency. Other causes of increased tHcy should be considered.

Measurement of Total Homocysteine

Physiologically, homocysteine exists in reduced, oxidized, and protein-bound forms.[193] Methods for tHcy were first introduced in the mid1980s that resolved the problems related to the presence of multiple unstable Hcy species in plasma by converting all Hcy species into the reduced form, HcyH, which is measured as an indication of tHcy content.[235,240,287] Consequently, modern methods require pretreatment of plasma or serum specimens with a reducing agent, such as dithioerythritol, dithiothreitol, mercaptoethanol, tributyl phosphine, and tris(2-carboxyl-ethyl) phosphine that converts all Hcy species into the reduced form, HcyH, which is measured as an indication of tHcy content.

Modern tHcy methods include enzyme immunoassays and chromatographic-based methods.[231,306,308] In practice, immunoassays[80] are most often used for routine purposes (e.g., fluorescence polarization immunoassay [FPIA] as run on Abbott's IMx and AxSYM platforms).[227,278] Chromatographic assays include amino acid analysis; high-performance liquid chromatography (HPLC) with ultraviolet, fluorescence, or electrochemical detection[9,76,307,308,316]; capillary electrophoresis with fluorescence detection; gas chromatography-mass spectrometry (GC-MS); and liquid chromatography with tandem MS (MS-MS).[42,70,231,308]

The different tHcy methods give comparable results[210,229,306] but there is a necessity for standardization of the tHcy assay.[306] A certified reference material is not currently available, but an IFCC working group is preparing such reference materials.

To obtain accurate results, it is recommended that specimens be refrigerated and quickly centrifuged.[193] If specimens are allowed to stand at room temperature, glycolysis can double homocysteine levels. Addition of fluoride or specific *S*-adenosylhomocysteine hydrolase inhibitors will prevent problems caused by glycolysis.[193] The short-term and long-term variability of plasma homocysteine measurements has been discussed.[86]

Reference intervals for fasting homocysteine levels have been reported to be 13 to 18 µmol/L for serum[212,308] and 10 to 15 µmol/L for plasma.[62] The reference interval for total homocysteine in pediatric patients has been reported to be 3.7 to 10.3 µmol/L.[317]

CHAPTER 27

Electrolytes and Blood Gases

Mitchell G. Scott, Ph.D., Vicky A. LeGrys, D.A., M.T.(A.S.C.P.), C.L.S.(N.C.A.) and James Stacey Klutts, M.D., Ph.D.

Maintenance of water homeostasis is paramount to life for all organisms. In mammals, the maintenance of osmotic pressure and water distribution in the various body fluid compartments is primarily a function of the four major electrolytes, Na^+, K^+, Cl^-, and HCO_3^-. In addition to water homeostasis, these electrolytes play an important role in the maintenance of pH, proper heart and muscle function, oxidation-reduction reactions, and as cofactors for enzymes. Indeed, there are almost no metabolic processes that are not dependent on or affected by electrolytes. Abnormal concentrations of electrolytes may be either the cause or the consequence of a variety of disorders. Thus determination of electrolytes is one of the most important functions of the clinical laboratory. Interpretation of abnormal osmolality and acid-base values requires specific knowledge of the electrolytes. Because of their physiological and clinical interrelationship, this chapter discusses determination of electrolytes, osmolality, acid-base status, and blood oxygenation.

ELECTROLYTES

Electrolytes are classified as either *anions*, negatively charged ions that move toward an anode, or *cations*, positively charged ions that move toward a cathode. Physiological electrolytes include Na^+, K^+, Ca^{2+}, Mg^{2+}, Cl^-, HCO_3^-, $H_2PO_4^-$, HPO_4^{2-}, and SO_4^{2-} and some organic anions, such as lactate. Although amino acids and proteins in solution also carry an electrical charge, they are usually considered separately from electrolytes. Hydrogen ion (H^+) concentration is routinely measured as pH, but its concentration is so low relative to other ions (10^{-9} versus 10^{-3} mol/L) in body fluids that it is not considered an electrolyte per se. The major electrolytes (Na^+, K^+, Cl^-, HCO_3^-) occur primarily as free ions, whereas significant amounts (>40%) of Ca^{2+}, Mg^{2+}, and trace elements are bound by proteins, such as albumin.

Determination of body fluid concentrations of the four major electrolytes (Na^+, K^+, Cl^-, and HCO_3^-) is commonly referred to as an "electrolyte profile." Other electrolytes that have special functions in particular contexts are discussed elsewhere: Ca^{2+}, magnesium, and phosphates in Chapter 49; iron in Chapter 31; trace elements in Chapter 30; and amino acids in Chapter 20.

Specimens for Electrolyte Determinations

Serum and *plasma*, obtained from blood collected by venipuncture into an evacuated tube, are the usual specimens analyzed for Na^+, K^+, Cl^-, and HCO_3^-. Capillary blood, collected in either microsample tubes, capillary tubes, or applied directly from a finger stick to some point-of-care devices, is also a common sample analyzed. Heparinized whole blood arterial or venous specimens obtained for blood gas and pH determinations may also be used with direct ion-selective electrodes (ISEs). Differences of values between serum and plasma and between arterial and venous samples have been documented for these electrolytes (see Tables 2-3 and 2-4), but only the differences between serum and plasma K^+ can be considered clinically significant. Heparin, either the lithium or ammonium salt, is required if plasma or whole blood is assayed. Use of plasma or whole blood has the advantage of shortening turnaround time, because it is not necessary to wait for the blood to clot.[81] Furthermore, plasma or whole blood has a distinct advantage in determining K^+ concentrations, which are invariably higher in serum depending on platelet count.[42,80]

Specimen tubes should be centrifuged unopened, and the serum or plasma separated promptly. Grossly lipemic blood can be a source of analytical error with some methods (see

later section on Electrolyte Exclusion Effect), making ultracentrifugation of serum or plasma before analysis necessary for lipemic samples. Hemolysis causes erroneously high K^+ results and this problem is often undetected when analyzing whole blood. In addition, unhemolyzed specimens that are not promptly processed may have increased K^+ concentrations because of K^+ leakage from red blood cells when whole blood is stored at 4 °C. These concerns and others regarding specimen collection and handling are addressed in the following pages with respect to individual analytes.

Urine collection for Na^+, K^+, or Cl^- assay should be made without the addition of preservatives. Feces and aspirates and drainages from different portions of the gastrointestinal tract may also be submitted for electrolyte analysis. Collection and analysis of sweat are described later in this chapter.

SODIUM

Sodium is the major cation of extracellular fluid. Because it represents approximately 90% of the ~154 mmol of inorganic cations per liter of plasma, Na^+ is responsible for almost one half the osmotic strength of plasma. It therefore plays a central role in maintaining the normal distribution of water and the osmotic pressure in the extracellular fluid compartment. The normal daily diet contains 8 to 15 g (130 to 260 mmol) of NaCl, which is nearly completely absorbed from the gastrointestinal tract. The body requires only 1 to 2 mmol/day, and the excess is excreted by the kidneys, which are the ultimate regulators of the amount of Na^+ (and thus water) in the body.

Sodium is freely filtered by the glomeruli. Seventy to 80% of the filtered Na^+ load is then actively reabsorbed in the proximal tubules, with Cl^- and water passively following in an isoosmotic and electrically neutral manner. Another 20% to 25% is reabsorbed in the loop of Henle along with Cl^- and more water. In the distal tubules, interaction of the adrenal hormone aldosterone with the coupled Na^+-K^+ and Na^+-H^+ exchange systems directly results in the reabsorption of Na^+, and indirectly of Cl^-, from the remaining 5% to 10% of the filtered load. It is the regulation of this latter fraction of filtered Na^+ that primarily determines the amount of Na^+ excreted in the urine. These processes are discussed in detail in Chapter 45.

Specimens

Serum, heparinized plasma, whole blood, sweat, urine, feces, or gastrointestinal fluids may be assayed for Na^+. Timed collections of urine, feces, or gastrointestinal fluids are preferred to allow comparison of values with reference intervals and to determine rates of electrolyte loss. Serum, plasma, and urine may be stored at 2 °C to 4 °C or frozen. Erythrocytes contain only one tenth of the Na^+ present in plasma, so hemolysis does not cause significant errors in serum or plasma Na^+ values. Lipemic samples should be ultracentrifuged and the infranatant analyzed unless a direct ISE is used.

Fecal and gastrointestinal fluid specimens require preparation before assay. Only liquid stools justify the trouble of analysis, because it is only when liquid feces occur that losses of electrolytes are significant. Immediately after collection, liquid stool specimens should be clarified of particulate matter by filtration through gauze or filter paper and by centrifugation. Because the risk of bacterial contamination of the automated instrument sampling systems is high with fecal samples, special cleaning and flushing procedures should follow analysis. Another difficulty with these specimens is their unpredictable concentration, which may necessitate a number of different dilutions to bring the concentration within the analytical range of the method. If not analyzed immediately, fecal and gastrointestinal fluids should be stored frozen to prevent microbial growth.

Determination of Sodium in Body Fluids

Sodium may be determined by atomic absorption spectrophotometry (AAS), flame emission spectrophotometry (FES), electrochemically with an Na^+-ISE, or spectrophotometrically. Of these methods, ISE methods are by far the most common. Excellent accuracy and coefficients of variation of less than 1.5% are readily achieved with modern equipment, reliable calibrators, and a good quality assurance program. Because sodium and potassium are routinely assayed together, methods for their analysis are described together later in this chapter.

Reference Intervals[65,101]

The interval for *serum* Na^+ is 136 to 145 mmol/L from infancy throughout life in one reference[101] and 135 to 145 mmol/L in another.[65] The interval for premature newborns at 48 hours is 128 to 148 mmol/L, and the value for umbilical cord blood from full-term newborns is ~127 mmol/L.

Urinary sodium excretion varies with dietary intake, but for people on an average diet containing 8 to 15 g/day, an interval of 40 to 220 mmol/day is typical.[101] There is a large diurnal variation in Na^+ excretion, with the rate of Na^+ excretion during the night being only 20% of the peak rate during the day. The Na^+ concentration of cerebrospinal fluid is 136 to 150 mmol/L. Mean fecal Na^+ excretion (for eight healthy subjects) has been reported as 7.8 ± 2.0 mmol/day (standard error) in one study,[19] and less than 10 mmol/day in another.[101]

POTASSIUM

Potassium is the major intracellular cation. In tissue cells, its average concentration is 150 mmol/L, and in erythrocytes, the concentration is 105 mmol/L (~23 times its concentration in plasma). High intracellular concentrations are maintained by the Na^+, K^+ adenosine triphosphate (ATP)ase pump, which is fueled by oxidative energy and continually transports K^+ into the cell against the concentration gradient. This pump is a critical factor in maintaining and adjusting the ionic gradients on which nerve impulse transmission and contractility of cardiac and skeletal muscle depend. Dif-

fusion of K^+ out of the cell into the plasma exceeds pump-mediated K^+ uptake whenever pump activity is decreased because of (1) depletion of metabolic substrates, such as glucose, for ATP production; (2) competition for ATP between the pump and other energy-consuming activities of the cell; or (3) when cellular metabolism is slowed (as occurs with refrigeration). The importance of these considerations on sample integrity for analysis of K^+ is discussed later in this chapter.

The body requirement for K^+ is satisfied by a dietary intake of 50 to 150 mmol/day. Potassium absorbed from the gastrointestinal tract is rapidly distributed, with a small amount taken up by cells and most excreted by the kidneys. Potassium filtered through the glomeruli is almost completely reabsorbed in the proximal tubules and is then secreted in the distal tubules in exchange for Na^+ under the influence of aldosterone. Aldosterone enhances K^+ secretion and Na^+ reabsorption in the distal tubules by an Na^+-K^+ exchange mechanism. The kidneys respond almost immediately to K^+ loading with an increase in K^+ output, so that urine collected during or after a period of high intake may have a K^+ concentration as high as 100 mmol/L. In contrast, the tubular response to conserve K^+ in instances of depletion is very slow in the initial stages, with the normal kidney continuing to excrete K^+ at a rate of 20 to 30 mmol/day. Unlike the prompt response of the tubules to conserve Na^+ in deficit states, it can take up to 1 week for the tubules to reduce K^+ excretion to 5 to 10 mmol/day.

Factors that regulate distal tubular secretion of K^+ are intake of Na^+ and K^+, plasma concentration of mineralocorticoids, and acid-base balance. Because renal conservation mechanisms are slow to respond, K^+ depletion can be an early consequence of restricted K^+ intake or losses of K^+ by extrarenal routes. Diminished glomerular filtration rate is typical of renal failure, and the consequent decrease in distal tubular flow rate is an important factor in the retention of K^+ seen in chronic renal failure. Renal tubular acidosis and metabolic and respiratory acidoses and alkaloses also affect renal regulation of K^+ excretion. These topics are discussed in much greater detail in Chapters 45 and 46.

Specimens

Comments made earlier on specimens for Na^+ analysis are generally applicable to those for K^+ analysis. However, some additional points must be considered.

Potassium concentrations in plasma and whole blood are 0.1 to 0.7 mmol/L lower than those in serum and stated reference intervals for serum K^+ are 0.2 to 0.5 mmol/L higher than those for plasma K^+. The extent of this difference depends, however, on the platelet count, because the additional K^+ in serum is primarily a result of platelet rupture during coagulation.[42,48,80] This variability in the amount of additional K^+ in serum makes plasma the specimen of choice and emphasizes the necessity of noting on reports whether serum or plasma was assayed and using the appropriate reference intervals.

Specimens for determining K^+ concentrations in serum or plasma must be collected by methods that minimize hemolysis, because release of K^+ from as few as 0.5% of the erythrocytes can increase K^+ values by 0.5 mmol/L. An increase in K^+ of 0.6% has been estimated for every 10 mg/dL of plasma hemoglobin (Hb) caused by hemolysis.[16] Thus slight hemolysis (~50 mg Hb/dL) can be expected to raise K^+ values ~3%, marked hemolysis (~200 mg Hb/dL) 12%, and gross hemolysis (>500 mg Hb/dL) as much as 30%. Therefore it is imperative that any visible hemolysis be noted with reported K^+ values and include a comment that results are falsely elevated. If K^+ concentrations are determined by ISE on whole blood specimens using a blood gas instrument or a point-of-care device, increases in actual K^+ concentrations caused by hemolysis may be easily overlooked. Whenever hemolysis is suspected, a portion of the specimen should be centrifuged and visually inspected.

Clinically significant preanalytical errors can occur in K^+ determinations if blood samples are not processed expediently.[41] As mentioned earlier, maintenance of the intracellular-extracellular K^+ gradient depends on the activity of the energy-dependent Na^+,K^+ ATPase. If a whole blood specimen is chilled before separation, glycolysis is inhibited and the energy-dependent Na^+,K^+ ATPase cannot maintain this gradient and increases in plasma K^+ will occur as a result of K^+ leakage from erythrocytes and other cells. The increase of K^+ in serum is of the order of 0.2 mmol/L in 1.5 hours at 25 °C, whereas at 4 °C, the increase is considerably greater, and has been reported to be as much as a 2-mmol/L increase after 4 hours at 4 °C.[84]

The opposite effect, namely a falsely decreased K^+ value, is initially observed if an unseparated sample is stored at 37 °C because glycolysis occurs and K^+ shifts intracellularly. Even at room temperature, leukocytosis can initially cause falsely decreased K^+ concentrations. The extent of this decrease depends on leukocyte count, temperature, and glucose concentrations, but has been reported to be as much as 0.7 mmol/L at 37 °C.[58] This effect is, however, biphasic. Initially, plasma K^+ decreases as a result of glycolysis, but after the glucose substrate is exhausted K^+ will leak from cells.[3] When the leukocyte count is greater than 100,000/μL and hypokalemia is already a characteristic of the disease (as in acute myeloid leukemia), glycolysis at room temperature may cause the K^+ deficit to seem greater than it actually is. Taking together the effects of glycolysis causing an initial intracellular shift of K^+ followed by K^+ leakage from cells because of glucose exhaustion or inhibition of glycolysis by refrigeration, the recommendation for the most reliable K^+ determinations is to collect blood with heparin to maintain it between 25 °C and 37 °C, and to separate the plasma within minutes by high-speed centrifugation without cooling. However, in practical terms, separation within 1 hour when samples are maintained at room temperature is unlikely to introduce great error in the majority of instances.

Finally, skeletal muscle activity causes K^+ efflux from muscle cells into plasma and can cause a marked elevation

in plasma K^+ values. One particular, but common, example occurs when an upper arm tourniquet is not released before beginning to draw blood after a patient clenches his fist repeatedly. The plasma K^+ values can artifactually increase as much as 2 mmol/L because of the muscle activity.[31]

Determination of Potassium in Body Fluids

Like sodium, potassium may be determined by spectrophotometry, AAS, FES, or electrochemically with a K^+-ISE. The ISE method is currently the most common by far. In the physiological range, it should be possible with modern equipment and good quality assurance to achieve coefficients of variation of less than 2% for plasma. Details are described later in this chapter along with the methods for Na^+.

Reference Intervals[65,101]

Reported reference intervals for the serum of adults vary from 3.5 to 5.1 and 3.5 to 5.0 mmol/L, and 3.7 to 5.9 for newborns. For plasma, frequently cited intervals are 3.5 to 4.5 and 3.4 to 4.8 mmol/L for adults. Cerebrospinal fluid concentrations are ~70% of plasma.[106] Urinary excretion of K^+ varies with dietary intake, but a typical range observed in an average diet is 25 to 125 mmol/day. Gastric juice contains K^+ at ~10 mmol/L. Fecal excretion has been reported as 18.2 ± 2.5 mmol/day in one instance[19] and ~5 mmol/day in another.[101] In severe diarrhea, gastrointestinal loss may be as much as 60 mmol/day.

Methods for the Determination of Sodium and Potassium

Although AAS, FES, or spectrophotometric methods may be used for Na^+ and K^+ analysis, most laboratories now use ISE methods. Of approximately 5400 laboratories reporting College of American Pathologists (CAP) proficiency data for Na^+ and K^+, >99% were using ISE methods in 2003.[22] The principles of each of these approaches (which are discussed in detail in Chapters 3 and 4) are the same whether the instrumentation is dedicated or integrated into a multichannel system.

Flame Emission Spectrophotometry

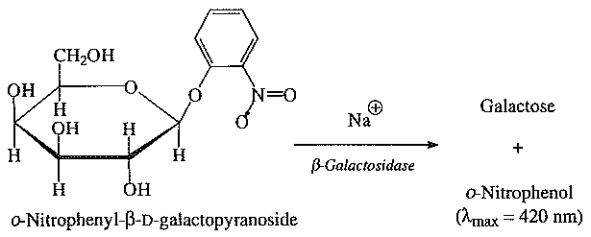
Reference methods using flame photometry for serum have been proposed for both sodium and potassium.[78] Although at one time the most common method for Na^+ and K^+ analysis, FES is no longer a common laboratory method. Advances in electrochemistry combined with the high amount of maintenance and safety procedures for FES have essentially led to the demise of this method for electrolyte analysis.

Principle. Samples are diluted in a diluent containing known amounts of lithium (or cesium, if lithium itself is being measured) and aspirated into a propane-air flame. Sodium, potassium, lithium, and cesium ions, when excited, emit spectra with sharp, bright lines at 589, 768, 671, and 852 nm, respectively. Light emitted from the thermally excited ions is directed through separate interference filters to corresponding photodetectors. The Li^+ or Cs^+ emission signal is used as an internal standard (usually 15 mmol/L) against which the Na^+ and K^+ signals are compared. The system is calibrated relative to low and high concentrations of each analyte, and the relation of signal to concentration is defined by a microprocessor (see also Chapter 3). Details about reagents, procedures, and laboratory safety issues for flame photometry can be found in the third edition of this text (pp. 1059-1060).[18]

Ion-Selective Electrodes[66,68]

Analyzers fitted with ISEs usually contain Na^+ electrodes with glass membranes and K^+ electrodes with liquid ion-exchange membranes that incorporate valinomycin. (Typical electrodes and the principles of potentiometry are described in detail in Chapter 4.) Simply stated, potentiometry is the determination of change in electromotive force (*E*, potential) in a circuit between a measurement electrode (the ISE) and a reference electrode, as the selected ion interacts with the membrane of the ISE. In instrument applications, the measuring system is calibrated by introduction of calibrator solutions containing defined amounts of Na^+ and K^+. The potentials of the calibrators are determined, and the $\Delta E/\Delta$ log concentration is stored in microprocessor memory as a factor for calculating unknown concentration when *E* of the unknown is measured. Frequent calibration, initiated either by the user or by automated, microprocessor-controlled uptake of sample from a reservoir of calibrator, is characteristic of most systems. Some instruments are designed to measure Na^+ and K^+ in whole blood, particularly point-of-care testing (POCT) devices and newer blood gas analyzers.

Two types of ISE methods must be distinguished. In the *indirect ISE methods,* the sample is introduced into the measurement chamber after mixing with a rather large volume of diluent. Examples include the Beckman Coulter Synchron CX and LX systems, the Roche Diagnostic Hitachi Modular systems, and the Olympus Diagnostics AU systems. Indirect methods were developed earlier in the history of ISE technology when dilution was necessary to present a small sample in a volume large enough to adequately cover a large electrode and to minimize the concentration of protein at the electrode surface. In the *direct ISE methods,* the sample is presented to the electrodes without dilution. This approach became possible with the miniaturization of electrodes. Examples of direct ISEs include those on blood gas analyzers, such as the Radiometer ABL series, the Instrumentation Laboratories GEM series, and the Bayer Diagnostics Rapid Lab series. Single-use, thin-film ISEs for Na^+, K^+, and Cl^- are unique applications of a direct ISE method that are used by the Ortho Diagnostic's Vitros analyzers.[23] In 2003, of the 5400 laboratories reporting CAP proficiency sample results for Na^+ and K^+, ~two thirds used indirect ISEs and one third used direct ISE methods.[22] Important differences in direct and indirect methods that



can cause significant differences in analytical results are discussed in the later section on the electrolyte exclusion effect.

Errors observed in the use of ISEs fall into three categories. First are errors caused by lack of selectivity. For instance, many Cl^- electrodes lack selectivity against other halide ions. Second are errors introduced by repeated protein coating of the ion-sensitive membrane, or by contamination of the membrane or salt bridge by ions that compete or react with the selected ion and thus alter electrode response. These necessitate periodic changes of the membrane as part of routine maintenance. Finally, the "electrolyte exclusion effect," which applies only to indirect methods and is caused by the solvent-displacing effect of lipid and protein in the sample, results in falsely decreased values[5] (see the section on the electrolyte exclusion effect later in this chapter).

Spectrophotometric Methods

Spectrophotometric methods fall into three categories: those based on enzyme activation, those that detect the spectral shift produced when either Na^+ or K^+ binds to a macrocyclic chromophore, and fluorescent sensors. Both approaches have been applied to smaller automated instruments. However, the high cost of reagents for these methods and the fact that few problems exist with ISE methods has resulted in small "niche" use of these methods, primarily in some smaller instruments used in physicians' offices or clinics.

Kinetic spectrophotometric assays for Na^+ are based on activation of the enzyme β-galactosidase by Na^+ to hydrolyze *o*-nitrophenyl-β-D-galactopyranoside (ONPG).[9,85] The rate of production of *o*-nitrophenol (the chromophore) is measured at 420 nm.

K^+-specific enzyme activation assays are illustrated by methods using tryptophanase,[53] one of a number of K^+-enhanced enzymes.[8] Accuracy and precision of the method have been reported to compare favorably with those achieved with flame photometry.[47] Bilirubin and hemoglobin and other cations are said to have little effect as interferants, but lipemic samples could not be analyzed.[47]

Macrocyclic ionophores are molecules whose atoms are organized to form a cavity into which metal ions fit and bind with high affinity. Such compounds are also called *polycyclic ethers, crown ethers, cryptands,* or *cryptahemispherands.* Different macrocyclics can be made with cavities tailored to fit the ionic radii of different elements. When chromogenic properties are imparted to these ionophores, spectral shifts occur when the cation is bound. The specificity of many of these ionophores is clearly sufficient for clinical purposes.[55]

One proprietary chromogenic ionophore, *ChromoLyte,* a trinitroanilino-cryptahemispherand, is selective for Na^+ and has been used in some instruments (Bayer Diagnostics, Tarrytown, N.Y.), whereas others are used on smaller, physician's office type of instruments, such as the Abbott Vision (Abbott Laboratories) or Bayer Seralyzer (Bayer Diagnostics, Elkhart, Ind.). These methods give results comparable with methods using ISEs.[55] Potassium can be measured with the same method but using an ionophore with a different cavity size.[55] In fact, an early clinical application of the macrocyclic ionophore principle is the valinomycin ISE for K^+ (see Chapter 4). The Reflotron analyzer (Roche Diagnostics) uses valinomycin in conjunction with a pH indicator to determine serum K^+ concentration. If the cyclic compound has a high binding constant for K^+ and the properties of a chromophore, the process of binding K^+ causes a spectral shift as the molecular structure or ionic form (or both) of the chromophore adjusts to the presence of K^+ in the cavity. Although unsuitable for urine because NH_4^+ is an interferant, results for K^+ in the serum appear to correlate well with those of flame photometric and direct and indirect ISE methods.[96] Finally, fluorescent sensor molecules whose fluorescence is altered by specific binding of electrolytes is the principle of measurement in the OPTI critical care analyzer for POCT from Osmetech, Inc.

Electrolyte Exclusion Effect[5]

The electrolyte exclusion effect is the exclusion of electrolytes from the fraction of the total plasma volume that is occupied by solids. The volume of total solids (primarily protein and lipid) in an aliquot of plasma is approximately 7% so that ~93% of plasma volume is actually water. The main electrolytes (Na^+, K^+, Cl^-, HCO_3^-) are essentially confined to the water phase. When a fixed volume of total plasma (e.g., 10 µL) is pipetted for dilution before flame photometry or indirect ISE analysis, only 9.3 µL of plasma water containing the electrolytes is actually added to the diluent. Thus a concentration of Na^+ determined by flame photometry or indirect ISE to be 145 mmol/L is the concentration in the total plasma volume, *not* in the plasma water volume. In fact, if the plasma contains 93% water, the concentration of Na^+ in plasma water is $145 \times (100/93)$, or 156 mmol/L. This negative "error" in plasma electrolyte analysis has been recognized for many years.[4] Even though it is the electrolyte concentration in plasma water that is physiological, it is tacitly assumed that the volume fraction of water in plasma is sufficiently constant that this difference could be ignored. In fact, all electrolyte reference intervals are based on this assumption and actually reflect concentrations in total plasma volume and not in the water volume. Indeed, virtually all concentrations measured in the clinical chemistry laboratory are related to the total sample volume rather than to the water volume. This electrolyte exclusion effect becomes problematic when pathophysiological condi-

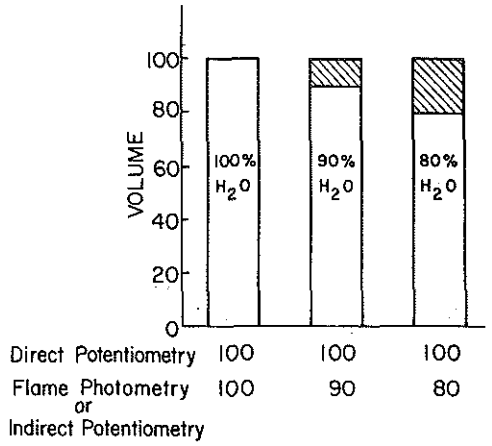


Figure 27-1 Predicted influence of water content on sodium measurements for a 100 mmol/L NaCl solution by direct ion-selective electrode (ISE versus flame emission photometry or indirect ISE). *Hatched areas* represent nonaqueous volumes, which could consist of lipids, proteins, or even a slurry of latex or sand particles. *(From Apple FS, Koch DD, Graves S, Ladenson JH. Relationship between direct-potentiometric and flame-photometric measurement of sodium in blood. Clin Chem 1982;28:1931-5.)*

TABLE 27-1 Methods Measuring the Concentration in the Whole Sample Volume and Thus Subject to Electrolyte Exclusion Effect

Method	Analytes
Flame photometry	Na^+, K^+, Li^+
Atomic absorption spectrometry	Ca^{2+}, Mg^{2+}, and others
Amperometry/coulometry	Cl^-
Indirect potentiometry	Na^+, K^+, Ca^{2+}, Cl^-

tions are present that alter the plasma water volume, such as hyperlipidemia or hyperproteinemia. In these settings, falsely low electrolyte values are obtained whenever samples are diluted before analysis, as in flame photometry or indirect ISE[5] (Figure 27-1).

Indirect ISE methods dilute the sample in a diluent of fixed high ionic strength so that for Na^+, the activity coefficient approaches a value of 1. Under these circumstances, the measurement of activity, a (where $a = \gamma \times$ concentration, and γ is the activity coefficient), is tantamount to measurement of concentration. Flame photometry measures emission of a specific ion after dilution in solutions of high reference ion concentration so that specific emission is also tantamount to the measurement of concentration of the specific ion in total plasma volume. It is the dilution of total plasma volume and the assumption that plasma water volume is constant that render both indirect ISE and flame photometry methods equally subject to the electrolyte exclusion effect. In certain settings, such as ketoacidosis with severe hyperlipidemia[38] or multiple myeloma with severe hyperproteinemia,[57] the negative exclusion effect may be so large that laboratory results lead clinicians to believe that electrolyte concentrations are normal or low when, in fact, the concentration in the water phase may be high or normal, respectively.

The direct ISE methods still determine the concentration relative to activity but do not require sample dilution. Because there is no dilution, activity is directly proportional to the concentration in the water phase, not the concentration in the total volume. To make results from direct ISEs equivalent to flame photometry and indirect ISEs, most direct ISE methods operate in what is commonly referred to as the "flame mode." In this mode, the directly measured concentration in plasma water is multiplied by the average water volume fraction of plasma (0.93). Although the latter may vary widely, as long as the activity of the specific ion is constant, the concentration of the ion in the water phase becomes *independent* of the relative proportions of water and total solids if the ion is not bound by proteins, as is the case for Ca^{2+}. Therefore direct ISE methods are free of the electrolyte exclusion effects, and the values determined by direct ISE methods—even in the flame mode—are directly proportional to activity in the water phase and define electrolyte concentrations in a more physiological and physicochemical sense.

Most clinical chemists and physicians have reached a conclusion that direct ISE methods for electrolyte analysis are the methods of choice. They base their conclusion on the fact that great changes in plasma lipid, protein, and other solids can be expected in relatively common clinical conditions and in therapies such as parenteral alimentation with lipid emulsions. They emphasize further that even in the absence of great changes in the volume fraction of solids, results by direct methods most realistically reflect clinical status and are therefore more effectively used in diagnosis and management. However, it is clear that results from direct methods will continue to be converted to total plasma volume concentrations by use of the "flame mode," and indeed this is the recommendation of the National Committee for Clinical Laboratory Standards (NCCLS).[78] This is also a good recommendation since two thirds of laboratories still use indirect ISE methods[22] and since some reviewers mistakenly believe that modern clinical laboratories are no longer subject to this cause of falsely decreased electrolyte values.[15] Tables 27-1 and 27-2 summarize methods that are and are not subject to the electrolyte exclusion effects, respectively.

The most common causes of the electrolyte exclusion effect leading to pseudohyponatremia or pseudohypokalemia are hyperlipidemia[25] and hyperproteinemia.[58] In severe hypoproteinemia, the effect works in reverse, resulting in a falsely high (2% to 4%) Na^+ or K^+ value. Several approaches have been proposed to improve the physiological accuracy of electrolyte values determined by methods

TABLE 27-2 Methods Measuring the Activity, Molality, or Concentration in the Water Phase and Thus Not Subject to Electrolyte Exclusion Effect

Method	Analytes
ISEs with *undiluted* sample	H^+ (pH), Na^+, K^+, Ca^{2+}, Cl^-, Li^+
Gas electrodes	CO_2 (PCO_2), O_2 (PO_2)
	HCO_3^- (calculated from pH and PCO_2)
Freezing point depression	H_2O (osmolality)

subject to the electrolyte exclusion effect. For lipemic samples, centrifugation at 100,000 ×*g* and analysis of the chylomicron-poor infranatant is the most common approach.[4] When triglyceride concentrations are less than 1500 mg/dL the error is less than 3%, and it is less than 5% for triglyceride concentrations less than 2500 mg/dL.

In situations in which both lipid and protein content are altered, presenting plasma electrolyte values along with concurrent estimates of plasma water has been suggested. One approach to estimate plasma water is Waugh's empirical equation[107]:

$$\text{Plasma water [g/dL]} = 99.1 - 0.73(P_s) - 1.03(L_s)$$

where P_s is serum total protein and L_s is serum total lipid, both in grams per deciliter. Determination of plasma water by an osmometry-based method[4] is also possible, but cumbersome. A simple, though time-consuming, estimate of serum water can be done by gravimetry. A measured aliquot of serum is weighed, evaporated to dryness, and reweighed, the decrement in weight being the measure of the water fraction. In a practical sense, however, these steps are seldom done, and it is paramount that clinical chemists be aware of the electrolyte exclusion effect and be able to invoke special procedures in these cases to mitigate these errors. Alternatively, the best solution is to use a direct ISE method.

CHLORIDE

Chloride is the major extracellular anion, with median plasma and interstitial fluid concentrations of ~103 mmol/L. This represents by far the largest fraction of the total inorganic anion concentration of ~154 mmol/L. Together, sodium and chloride represent the majority of the osmotically active constituents of plasma. Therefore chloride is significantly involved in the maintenance of water distribution, osmotic pressure, and anion-cation balance in the extracellular fluid (ECF). In contrast to its high ECF concentrations, the concentration of Cl^- in the intracellular fluid of erythrocytes is 45 to 54 mmol/L, and in the intracellular fluid of most other tissue cells it is only ~1 mmol/L. In both gastric and small and large intestinal secretions, Cl^- is the most abundant anion.

Chloride ions in food are almost completely absorbed from the intestinal tract. They are filtered from plasma at the glomeruli and passively reabsorbed, along with Na^+, in the proximal tubules. In the thick ascending limb of the loop of Henle, Cl^- is actively reabsorbed by the chloride pump, whose action promotes passive reabsorption of Na^+. Loop diuretics such as furosemide and ethacrynic acid inhibit the chloride pump. Surplus Cl^- is excreted in the urine and is also lost in the sweat, especially in hot environments.

Methods for Determination of Chloride in Body Fluids

Chloride may be determined by mercurimetric titration, spectrophotometry, coulometric-amperometric titration, or, most commonly today, ISE.

Specimens

Chloride is most often measured in serum or plasma, urine, and sweat. Cl^- is quite stable in serum and plasma. Even gross hemolysis does not significantly alter serum or plasma Cl^- concentration because the erythrocyte concentration of Cl^- is approximately half of that in plasma. Because very little Cl^- is protein bound, changes in posture, stasis, or use of tourniquets also have little effect on its plasma concentration. Measurement of Cl^- lost in gastric aspirates or intestinal drainages is an adjunct to parenteral replacement therapy. Fecal Cl^- determination may be useful for the diagnosis of congenital hypochloremic alkalosis with hyperchloridorrhea (increased excretion of Cl^- in stool). In this condition, the concentration of Cl^- in feces may reach 180 mmol/L, with almost no Cl^- being found in urine.

Mercurimetric Titration

One of the earliest methods for determining Cl^- in biological fluids is mentioned here for historical purposes.[92] A protein-free filtrate of specimen is titrated with mercuric nitrate solution in the presence of diphenylcarbazone as an indicator. Free Hg^{2+} combines with Cl^- to form soluble but essentially nonionized mercuric chloride:

$$2Cl^- + Hg(NO_3)_2 \rightarrow HgCl_2 + 2NO_3^-$$

Excess Hg^{2+} reacts with diphenylcarbazone to form a blue-violet color complex. A more detailed description can be found in the first edition of this textbook (pp. 1184-1185).[100]

Spectrophotometric Methods

Spectrophotometric methods based on the reaction of Cl^- with mercuric thiocyanate used to be common on many automated analyzers. The principle is illustrated in the following equations:

$$Hg(SCN)_2 + 2Cl^- \rightarrow HgCl_2 + 2SCN^-$$

$$3(SCN)^- + Fe^{3+} \rightarrow Fe(SCN)_3$$

Chloride ions react with undissociated mercuric thiocyanate to form undissociated mercuric chloride and free thiocyanate ions. The thiocyanate ions react with ferric ion (Fe^{3+}) to form the highly colored, reddish complex of ferric thiocyanate with an absorption peak at 480 nm. Perchloric acid increases the intensity of the red color. High concentrations of globulins in the serum interfere in these methods because turbidity develops. This reaction is also very temperature sensitive.

Mercurimetric automated methods applied to high-volume testing presented the problem of disposal of reagent waste containing a significant amount of toxic mercury. The mercuric thiocyanate and nitrate methods constituted about 3% of the laboratories reporting Cl^- results in a 1996 CAP survey report but none of ~5400 laboratories used these methods according to a 2003 CAP report.[22] The ferric perchlorate method eliminates the mercurial reagent entirely.[59] Ferric perchlorate and Cl^- react in dilute perchloric acid to form a color complex with absorption maxima at 344 and 562 nm. The absorbance-concentration relationship is linear, and the reaction is more specific for Cl^- than many other spectrophotometric methods. However, this method is also no longer reported as being used in a 2003 CAP survey.[22]

Coulometric-Amperometric Titration

The reactions in coulometric-amperometric determinations of Cl^- depend on the generation of Ag^+ from a silver electrode at a constant rate and on the reaction of Ag^+ with Cl^- in the sample to form insoluble silver chloride[24]:

$$Ag^+ + Cl^- \rightarrow AgCl$$

After the stoichiometric point is reached, excess Ag^+ in the mixture triggers shutdown of the Ag^+ generation system. A timing device records the elapsed time between the start and stop of the Ag^+ generation. (A more detailed description of this principle can be found in Chapter 4.) Because the time interval is proportional to the amount of Cl^- present in the sample, the concentration of Cl^- can be calculated:

$$\text{Chloride (mmol/L)} = \frac{\text{time}_{\text{undnown}} - \text{time}_{\text{blank}}}{\text{time}_{\text{calibrator}} - \text{time}_{\text{blank}}} \times C_{\text{calibrator}}$$

where $C_{\text{calibrator}}$ is the concentration of calibrator.

Applications of the coulometric-amperometric principle (often called a Cotlove chloridometer[24]) are the most precise methods for measuring Cl^- over the entire range of concentrations displayed in body fluids. CAP surveys from 1996 showed coefficients of variation of ±1.3% to 1.5% ($n = 42$) for the Beckman ASTRA method and less than ±2.2% for the Corning Titrator (Chiron Diagnostics) over the concentration range of 102 to 119 mmol/L. Calibrator concentrations should, however, be chosen to correlate with the concentration range of unknowns. The method is subject to interferences by other halide ions, by CN^- and SCN^- ions, by sulfhydryl groups, and by heavy metal contamination. Because samples are prediluted before analysis, these methods are also subject to the electrolyte exclusion effect. Maintenance of the systems is crucial to proper operation; electrodes and reaction vials or chambers must be kept scrupulously clean and the proper shape and size of the Ag^+-generating electrodes must be maintained. Only 12 of 5400 laboratories reported in the 2003 CAP survey reported Cl^- results using coulometry.[22] However, some laboratories still maintain these instruments as backups and for sweat analysis.

Ion-Selective Electrode Methods

Solvent polymeric membranes that incorporate quaternary ammonium salt anion-exchangers, such as tri-*n*-octylpropylammonium chloride decanol, are used to construct Cl^--selective electrodes in clinical analyzers.[83] Although by far the most common method for measuring Cl^- in clinical laboratories, these electrodes have been described to suffer from membrane instability and lot-to-lot inconsistency in selectivity to other anions.[83,104] Anions that tend to be problematic are other halides and organic anions, such as SCN^-, which can be particularly problematic because of their ability to solubilize in the polymeric organic membrane of these electrodes.

Approximately 68% of 5394 laboratories reporting in a 2003 CAP proficiency test survey for Cl^- used indirect ISE methodology.[22] Instruments using the indirect ISE method for Cl^- on serum or plasma include the Dade Behring Dimension Series, the Roche Diagnostics Hitachi Modular System, the Beckman Coulter Synchron series, the Abbott Aeroset, and the Olympus AU series of analyzers. In 2003, 1646 of 5394 laboratories (32%) participating in a CAP proficiency survey used direct ISEs, and most of those were the Ortho Diagnostics Vitros series of dry slide analyzers, and blood gas analyzers with direct ISEs.

Reference Intervals[65,101]

Reported reference intervals for Cl^- in the serum or plasma range from 98 to 107 mmol/L to 100 to 108 mmol/L. For neonates, the upper limit of the interval extends to 110 mmol/L. The serum values vary little during the day. The spinal fluid Cl^- concentrations are ~15% higher than in the serum.[106] Urinary excretion of Cl^- varies with dietary intake, but an interval of 110 to 250 mmol/day is typical. Fecal excretion of Cl^- (for eight healthy subjects) has been reported as 3.2 ± 0.7 mmol/day (SEM)[19] and elsewhere as ~2 mmol/day.[101]

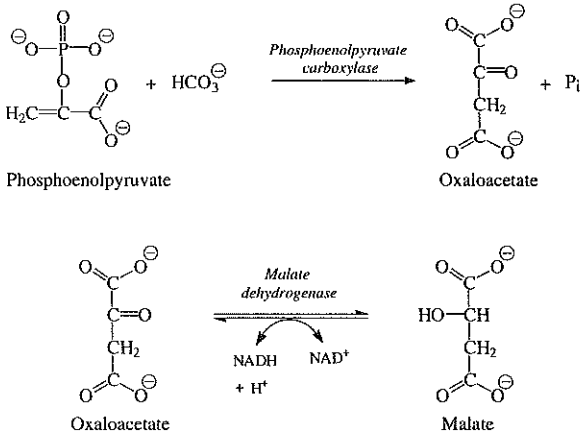
Bicarbonate (Total Carbon Dioxide)

Total carbon dioxide is used here to describe the quantity that is measured most often in automated analyzers by acidification of a serum or plasma sample and measurement of the carbon dioxide released by the process, or by alkalinization and measurement of total bicarbonate. Under certain conditions of collection and specimen handling, total carbon dioxide values determined in this manner may be almost identical with values for the calculated concentration of total carbon dioxide obtained in blood gas analysis (see later section in this chapter on blood gas methods). The patho-

physiology of bicarbonate in acid-base disorders is discussed in detail in Chapter 46.

Specimens

Either serum or heparinized plasma may be assayed. The usual specimen is venous blood drawn into an evacuated tube, although capillary blood taken in microtubes or capillary tubes may also be presented for analysis. Given a specimen in a vacuum-draw tube, the concentration of total CO_2 is most accurately determined when the assay is done immediately after opening the tube and as promptly as possible after collection and centrifugation of the blood in the unopened tube. Ambient air contains far less CO_2 than does plasma, and gaseous dissolved CO_2 will escape from the specimen into the air, with a consequent decrease in the CO_2 value of up to 6 mmol/L in the course of 1 hour.[102] In practical terms, the logistics of high-volume processing and automated analysis of specimens almost ensures that most CO_2 measurements are done on specimens that have lost some dissolved gaseous CO_2, simply because preservation of anaerobic conditions is not practical between the time plasma is placed on an instrument and the time it is sampled. Thus the term "bicarbonate" may actually be preferable to "total CO_2." On the other hand, it is probable that the result of a stat specimen, which is rapidly processed and promptly analyzed, has a much smaller error.



Methods for Determination of Serum or Plasma Total Carbon Dioxide

One of the earliest methods for determining total CO_2 was the *manometric method* for total CO_2 content, using the Natelson microgasometer. This has been supplanted in clinical laboratories by automated methods. This method is described in some detail in an earlier edition of this text.[100]

The first step in automated methods is acidification or alkalinization of the sample. Acidifying the sample converts the various forms of CO_2 in plasma to gaseous CO_2 by dilution with an acid buffer. Alkalinizing the sample converts all CO_2 and carbonic acid to HCO_3^-.[43] The oldest automated methods were those used in *continuous-flow systems* in which the gaseous CO_2 diffused across a silicone membrane into a recipient solution buffered at pH 9.2 and containing the pH indicator phenolphthalein. The change in color over the baseline was determined by a photometer and is proportional to the amount of CO_2 released from the sample. These methods suffered from considerable baseline drift. Also, frequent reagent preparation and recalibration were necessary to keep the method in control. Air lines that supplied bubbles to the sample and reagent streams in these methods were fitted with a CO_2-absorbing trap, which had a short effective life. This method, although a mainstay of the 1960s and 1970s, is not used today.

Methods for total CO_2 measurement in today's automated instruments are either electrode based or enzymatic. In indirect electrode-based methods, such as the Beckman Coulter Synchron and Dade Behring Dimension series of analyzers, the released gaseous CO_2 after acidification is determined by a PCO_2 electrode (discussed in Chapter 4) in the reaction chamber of the CO_2 module. About 47% of 5211 laboratories reporting CAP data used an indirect ISE method in 2003.[22] These methods tend to be linear between ~5 and ~45 mmol/L. *Direct ISE methodology* for total CO_2 is not common on automated analyzers, with only 3% of laboratories from the 2003 CAP using this approach. Direct methods have had some problems with specificity. For instance, one direct total CO_2 electrode reacts almost equivalently with nitrate.[29]

An *enzymatic method* for CO_2 is illustrated by the methods used in the Abbott Aeroset, Bayer Advia, Roche Diagnostics Hitachi Modular, and most Ortho Diagnostics Virtos analyzers. The specimen is first alkalinized to convert all CO_2 and carbonic acid to HCO_3^-. The enzymatic reactions are as follows:

Decrease in absorbance of NADH at 340 nm is proportional to the total CO_2 content.

In 2003, these enzymatic methods are used by about 50% of all laboratories reporting total CO_2 values on CAP surveys.[22]

Reference Intervals[65,101]

Reference intervals generally are instrument dependent, and manufacturers' manuals should be consulted in specific cases. The following are reference intervals published in a compendium.[101]

Anaerobic Samples	mmol/L
Whole blood, venous	22-26
Whole blood, arterial	24-29
Plasma/serum, venous	23-29
Plasma, capillary	
Premature, 1 wk	14-27
Newborn	13-22
Infant, child	20-28
Adult	22-29
Adult, >60 yr	23-31
Cord blood	14-22

PLASMA AND URINE OSMOLALITY

Determination of plasma and urine osmolality can be useful in the assessment of electrolyte and acid-base disorders. Comparison of plasma and urine osmolalities can determine the appropriateness and status of water regulation by the kidneys in settings of severe electrolyte disturbances, as might occur in diabetes insipidus or the syndrome of inappropriate antidiuretic hormone (SIADH) (see Chapters 45 and 50). The major osmotic substances in normal plasma are Na^+, Cl^-, glucose, and urea; thus expected plasma osmolality can be calculated from the following empirical equation:

$$\begin{aligned}\text{mOsmol/kg} = {} & 1.86\,(Na^+\,[\text{mmol/L}]) \\ & + \text{glucose}\,[\text{mmol/L}] \\ & + \text{urea}\,[\text{mmol/L}] \\ & + 9\end{aligned}$$

or

$$\begin{aligned}\text{mOsmol/kg} = {} & 1.86\,(Na^+\,[\text{mmol/L}]) \\ & + \text{glucose}\,[\text{mg/dL}]/18 \\ & + \text{urea N}\,[\text{mg/dL}]/2.8 \\ & + 9\end{aligned}$$

The 9 mOsmol/kg added to the above equation represents the contribution of other osmotically active substances in plasma, such as K^+, Ca^{2+}, and proteins, and 1.86 is two times the osmotic coefficient of Na^+, reflecting the contributions of both Na^+ and Cl^-. The reference interval for plasma osmolality is 275 to 300 mOsmol/kg. Comparison of measured osmolality with calculated osmolality can help identify the presence of an "osmolal gap," which can be important in determining the presence of exogenous osmotic substances. Comparison of calculated and measured osmolalities can also confirm or rule out suspected pseudohyponatremia caused by the previously discussed electrolyte exclusion effect.

Principles of Osmotic Pressure and Osmosis

Osmometry is a technique for measuring the concentration of solute particles that contribute to the osmotic pressure of a solution. Osmotic pressure governs the movement of solvent (water in biological systems) across membranes that separate two solutions. Different membranes vary in pore size and thus in their ability to select molecules of different size and shape. Examples of biologically important selective membranes are those enclosing the glomerular and capillary vessels that are permeable to water and to essentially all *small* molecules and ions, but not to large protein molecules. Differences in the concentrations of osmotically active molecules that cannot cross a membrane cause those molecules that can cross the membrane to move to establish an osmotic equilibrium. This movement of solute and permeable ions exerts what is known as osmotic pressure.

As an example, consider an aqueous solution of sucrose placed within a sac made up of a membrane permeable only to water, with an open vertical glass tube (a crude manometer) attached to the sac. If the sac is placed into a beaker of distilled water, water will move from the beaker across the membrane into the sucrose solution. The pressure of this solvent movement will cause the sucrose solution to rise some distance up the tube. At equilibrium, the gravitational pressure of the column of solution in the tube equals the osmotic pressure and prevents further net movement of water from the beaker. The height of the rise of the sucrose solution in the manometer tube is a measure of the *osmotic pressure* of the sucrose solution. This is the pressure that would have to be exerted on the sucrose side of the membrane to prevent the flow of water across the membrane.

Osmosis[105] is the process that constitutes the movement of solvent across a membrane in response to differences in osmotic pressure across the two sides of the membrane. Water migrates across the membrane toward the side containing more concentrated solute.

If the sucrose solution in the aforementioned membrane sac were replaced with a sodium chloride solution of the same molarity, the solution in the manometer would reach equilibrium at a point almost twice as high as that observed with sucrose because sodium chloride dissociates into two ions per molecule. If ion activity is unrestricted, the sodium chloride solution would have twice as many osmotically active particles (osmoles) for the same molecular concentration as the sucrose solution. In reality, the number of active particles is less than this (0.93 for NaCl), as explained later in this chapter. The total number of individual (solute) particles present in a solution per given mass of solvent, regardless of their molecular nature (i.e., nonelectrolyte, ion, or colloid), determines the total osmotic pressure of the solution. In blood plasma, for example, nonelectrolytes such as glucose and urea and even proteins contribute to the osmotic pressure of this body fluid.

Colligative Properties

In addition to increasing osmotic pressure when the solute is added to the solvent, the *vapor pressure* of the solution is *lowered* below that of the pure solvent. As a result of the change in vapor pressure, the *boiling point* of the solution is *raised* above that of the pure solvent, and the *freezing point* of the solution is *lowered* below that of the pure solvent.

These four properties of solutions—(1) increased osmotic pressure, (2) lowered vapor pressure, (3) increased boiling point, and (4) decreased freezing point—are called *colligative properties.* They all are directly related to the total number of solute particles per mass of solvent. For instance, a 1-molal solution in water boils at a temperature 0.52 °C higher and freezes at a temperature 1.858 °C lower than pure water. The vapor pressure of this solution is 0.3 mm Hg lower than the vapor pressure of pure water, which is 23.8 mm Hg at 25 °C. The osmotic pressure of the same solution is increased from zero to 17,000 mm Hg (22.4 atmospheres). The term *osmolality* expresses concentrations relative to *mass* of the solvent (1 osmolal solution is defined to contain 1 Osmol/kg H_2O), whereas the term *osmolarity* expresses concentrations

per volume of solution (1 osmolar solution is defined to contain 1 osmol/L solution). Osmolality (Osmol/kg H_2O) is a thermodynamically more exact expression because solution concentrations expressed on a weight basis are temperature independent, whereas those based on volume will vary with temperature. Although the term "osmolarity" is often used in medical literature, osmolality is what the clinical laboratory measures and is a more informative term.

An electrolyte in solution dissociates into two (in the case of NaCl) or three (in the case of $CaCl_2$) particles, and therefore the colligative effects of such solutions are multiplied by the number of dissociated ions formed per molecule. However, because of incomplete electrolyte dissociation and associations between the solute and solvent molecules, many solutions do not behave in the ideal case, and a 1-molal solution may give an osmotic pressure lower than theoretically expected. The osmotic activity coefficient is a factor used to correct for the deviation from the "ideal" behavior of the system:

$$\text{Osmolality} = \text{osmol/kg } H_2O = \phi nC$$

where

ϕ = osmotic coefficient
n = number of particles into which each molecule in the solution potentially dissociates
C = molality in mol/kg H_2O.

A table of osmotic coefficients of most solutes of biological interest has been compiled.[110]

Glucose and ethanol have osmotic coefficients of 1.00, whereas the ϕ for sodium chloride is 0.93 at the concentrations found in serum—thus the derivation of $1.86 \times Na^+$ (mmol) in the formula to calculate plasma osmolality (NaCl potentially contributes 2 osmotically active particles times 0.93 = 1.86). The total osmolality or osmotic pressure of a solution is equal to the sum of the osmotic pressures or osmolalities of all solute species present. The electrolytes Na^+, Cl^-, and HCO_3^-, which are present in relatively high concentration, make the greatest contribution to serum osmolality. Nonelectrolytes such as glucose and urea, which are present normally at lower molal concentrations, contribute less, and serum proteins contribute less than 0.5% of the total serum osmolality because even the most abundant protein is present at millimolar concentrations.

Theoretically, any of the four colligative properties (vapor pressure, boiling point, freezing point, or osmotic pressure) could be used as a basis for the measurement of osmolality. However, the freezing point depression is most commonly used in clinical laboratories because of its simplicity. Furthermore, freezing point depression is independent of changes in ambient temperature, unlike vapor pressure. (The vapor pressure of water is 17.5 mm Hg at 20 °C, 23.8 mm Hg at 25 °C, and 47.1 mm Hg at 37 °C.)

Freezing Point Depression Osmometer

The instrument used is a freezing point depression osmometer[1], but it is often referred to simply as an osmometer. The components of a freezing point depression osmometer (Figure 27-2) are as follows:

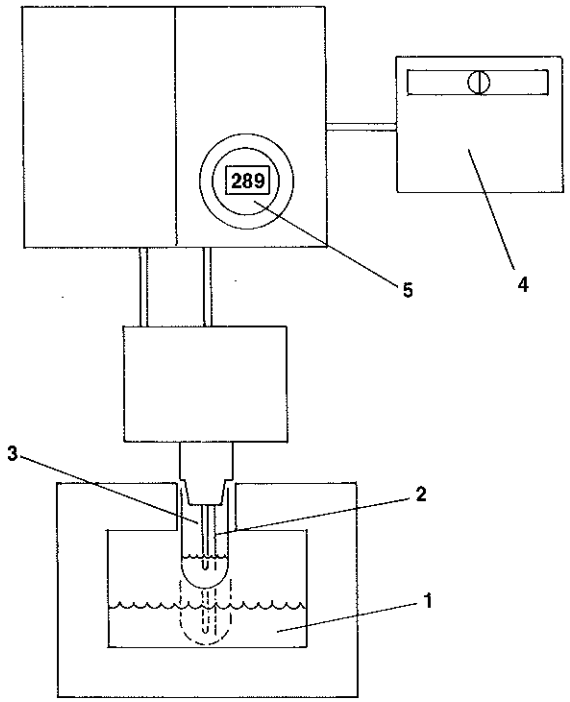


Figure 27-2 Block diagram of a freezing point depression osmometer. *1*, Cooling fluid; *2*, stirring rod; *3*, thermistor; *4*, galvanometer; *5*, potentiometer with direct readout. The test tube is shown above the liquid in the cooling bath *(solid line)* and inside the cooling liquid *(dashed line)*.

1. A thermostatically controlled cooling bath or block maintained at –7 °C.
2. A rapid stir mechanism to initiate ("seed") freezing of the sample.
3. A thermistor probe connected to a circuit to measure the temperature of the sample. (The thermistor is a glass bead attached to a metal stem whose resistance varies rapidly and predictably with temperature.)
4. A galvanometer that displays the freezing curve and that is used as a guide when the measuring potentiometer is used.
5. A measuring potentiometer (variable resistor) is used to null the current in the circuit.

In most instruments, components 4 and 5 are replaced by a light-emitting diode (LED) display that indicates the time course of the freezing curve and the final result.

During analysis, the following steps occur. The sample, in which the thermistor probe and stirring wire are centered, is lowered into the bath and, with gentle stirring, is super cooled to a temperature several degrees below its freezing point (–7 °C). When the galvanometer (or LED display) indicates that sufficient super cooling has occurred, the sample is raised to a point above the liquid in the cooling bath, and the wire stirrer is changed from a gentle rate of stir to a momentary vigorous amplitude, which initiates freezing

of the super-cooled solution. This freezing is only to the slush stage, with about 2% to 3% of the solvent solidifying. The released heat of fusion initially warms the solution and then the temperature plateaus and remains stationary, indicating the equilibrium temperature at which both freezing and thawing of the solution are occurring. At the end of the equilibrium temperature plateau, the galvanometer again indicates decreasing temperature as the sample freezes further toward a complete solid.

An example of the calculation to obtain osmolality is: if the observed freezing point is −0.53 °C, then

$$\text{mOsmol/kg } H_2O = \frac{-0.53}{-1.86} \times 1000 = 285$$

where −1.86 °C is the molal freezing point depression of pure water.

Day-to-day precision of ±2 mOsmol/kg H_2O should be obtainable by today's osmometers. More than 98% of the laboratories in the 2003 CAP surveys use freezing point depression osmometers, with the automated instrument from Advanced Instruments (Norwood, Mass.) being the most common.[22]

Vapor Pressure Osmometer

Another type of osmometer is the vapor pressure osmometer. In reality, osmolality measurement in these instruments is not related directly to a change in vapor pressure (in millimeters of mercury), but to the decrease in the *dew point temperature* of the pure solvent (water) caused by the decrease in vapor pressure of the solvent by the solutes. In this instrument, temperature is measured by means of a thermocouple, which is a device consisting of two dissimilar metals joined so that a voltage difference generated between the points of contact (junctions) is a measure of the temperature difference between the points.

In clinical laboratories, the vapor pressure osmolality technique has been reported to be less precise than the freezing point depression method.[69] For serum samples, the coefficients of variation obtained for the vapor pressure osmometer are about twice those obtained for the freezing point depression osmometer. The lesser degree of precision is related to the lower slope of dew point decrease compared with freezing point decrease (i.e., 0.303 °C versus 1.86 °C per osmol/kg H_2O).

An important clinical difference between the vapor pressure technique and the freezing point depression osmometer is the failure of the former to include in its measurement of total osmolality any volatile solutes present in the serum. Substances such as ethanol, methanol, and isopropanol are volatile, and thus escape from the solution and increase the vapor pressure instead of lowering the vapor pressure of the solvent (water). This makes use of vapor pressure osmometers impractical for identifying osmolal gaps in acid-base disturbances (see Chapter 46). Thus use of this type of osmometer cannot be recommended for most clinical laboratories.

Colloid Osmotic Pressure

Because of their large molecular weight, proteins contribute only about 1 mOsmol/kg H_2O to the total serum osmolality measured by freezing point depression. Occasionally, one may be asked to determine the contribution of macromolecules to the serum osmolality. Colloid osmotic pressure (COP) is a direct measure of the contribution of macromolecules (primarily proteins) to the serum osmolality. It is used primarily in the assessment of pulmonary edema or other abnormalities of water balance and serum protein concentrations.[73] However, its utility has been questioned[32] and the method is seldom used. Previous editions of this textbook describe the principles of a COP osmometer.[18,102]

SWEAT TESTING

The analysis of sweat for increased electrolyte concentration is used to confirm the diagnosis of cystic fibrosis (CF). CF is recognized as a syndrome with a wide spectrum of clinical presentations associated with a defect in the cystic fibrosis transmembrane conductance regulator protein (CFTR), a protein that normally regulates electrolyte transport across epithelial membranes. (For a more detailed discussion of CF, see Chapter 40.) Several hundred mutations of CFTR have been identified. Although mutational analysis is available, it is not informative in all cases, and the sweat test remains the standard for diagnostic testing.[89]

The United States Cystic Fibrosis Foundation (CFF) states that the diagnosis of CF is based on the following criteria[89]:

1. The presence of one or more characteristic phenotypic features
2. *Or* a history of CF in a sibling
3. *Plus* laboratory evidence of a CFTR abnormality as documented by elevated sweat chloride concentrations or identification of two CF mutations or in vivo demonstration of characteristic abnormalities in ion transport across the nasal epithelium

To provide appropriate care for CF patients and genetic counseling to their families, it is important that the diagnosis of CF be made accurately and promptly. In the United States, 70% of all CF patients are diagnosed by age 1. However, 8% of patients are diagnosed later than age 10, and more and more patients are being diagnosed as adults.[28] In addition to variable clinical presentation, the diagnosis of CF can be complicated by erroneous sweat-testing results. Unreliable methods, technical errors, and errors in interpretation can all lead to false results.[30,60,88] In an effort to standardize testing, the National Committee for Clinical Laboratory Standards (NCCLS) developed the guidelines document C34-A2: "Sweat Testing: Sample Collection and Quantitative Analysis."[79] The NCCLS document has been adopted by the CFF for use in its accredited care centers.[26] To encourage acceptable performance of the sweat test, the CAP Laboratory Accreditation Program has incorporated sweat collection and analysis into the Special Chemistry checklist.

TABLE 27-3 Methods of Sweat Analysis

Methods	Frequency
Chloride methods (N = 574)	
Chloridometer	199 (34.7%)
Direct skin electrode	197 (34.3%)
ISEs	59 (10.3%)
Manual titration	46 (8.0%)
Test patch	17 (3.0%)
Other	36 (6.3%)
Conductivity (N = 325)	
Wescor Sweat-Chek	206 (63.4%)
Advanced Instruments	60 (18.5%)
Other	59 (18.1%)
Sodium methods (N = 77)	
Flame photometer	41 (53.2%)
ISEs	29 (37.7%)
Other	7 (9.1%)
Osmolality (N = 64)	
Vapor pressure osmometer	47 (73.4%)
Freezing point depression osmometer	17 (26.6%)

From LeGrys VL, Burnett RW. Current status of sweat testing in North America. Arch Pathol Lab Med 1994;118:865-7. Copyright 1994, American Medical Association.
ISE, Ion-selective electrode.

The sweat test occurs in three phases: sweat stimulation by pilocarpine iontophoresis; collection of the sweat onto gauze, filter paper, coil, patch, or capillary tube; and qualitative or quantitative analysis of sweat chloride, sodium, conductivity, or osmolality. A survey of 753 laboratories (Table 27-3) performing sweat testing revealed that 47% analyze chloride, 46% analyze conductivity, and less than 7% analyze sodium or osmolality.[62]

Qualitative Screening Tests

Screening tests may or may not measure the amount of sweat collected and may report a result as positive, negative, or borderline, or give an actual concentration of sweat analytes. Patients having a positive or borderline screening result should have quantitative sweat testing. The use of reliable screening tests may have a role in smaller hospital laboratories where testing frequency does not lend itself to the maintenance of proficiency with quantitative analytical techniques. The CFF forbids accredited CF care centers from using screening sweat tests but rather requires those centers to perform quantitative analysis of sweat chloride.[26] Examples of qualitative screening sweat tests currently in use are the Wescor Sweat-Chek and Nanoduct conductivity analyzers (Wescor, Logan, Utah), the Advanced Instruments conductivity analyzer (Advanced Instruments), the Orion skin electrode for chloride (Orion Research, Cambridge, Mass.), the CF Indicator System chloride patch (Polychrome Medical, Brooklyn, Minn.) and sweat osmolality measurements. The Nanoduct instrument (Wescor) combines pilocarpine iontophoresis with a disposable conductivity cell. Although there are a variety of systems in use for sweat testing, several of the methods have documented problems, making them inappropriate for clinical use. For example, the Orion Skin Measuring System and older conductivity analyzers using unheated collection cups are not recommended as diagnostic procedures because problems have been reported with sample evaporation and condensation and the ability to quantify sweat samples adequately.[30,103,108]

The CFF has approved the Wescor Macroduct Sweat-Chek for screening at clinical sites, such as community hospitals, using the criteria that a patient having a sweat conductivity ≥50 mmol/L should be referred to an accredited CF care center for a quantitative sweat chloride test.[27] Wescor's recommended decision level is higher than that of the CFF, which can lead to confusion between the laboratory and physician as to the appropriate decision level.[14,63,111] The CFF medical advisory committee, in setting the decision limit at 50 mmol/L, did so cautiously, realizing that the goal of screening tests is to tolerate some false-positive results and minimize or prevent false-negative results. Situations with false-positive test results are resolved on further testing, but it would be unacceptable to miss a CF patient. When evaluating sweat conductivity results, it should be noted that values from sweat conductivity methods are approximately 15 mmol/L higher than sweat chloride concentration. The difference is most likely caused by the presence of unmeasured anions, such as lactate and bicarbonate.[44] Because of this difference, laboratories must be clear in reporting that the screening test result represents conductivity, not chloride, and must include appropriate sweat conductivity reference intervals. Confusion, anxiety, and the potential for misdiagnosis arise in patients and their families when a sweat conductivity is mistakenly evaluated using sweat chloride reference intervals. Sixty-eight percent of laboratories performing sweat conductivity had errors in result reporting that included using inappropriate decision levels, reporting conductivity as chloride, and using conductivity as a diagnostic, not screening test.[62]

Quantitative Confirmatory Tests

According to the NCCLS C34-A2 document,[79] a quantitative sweat test consists of collecting sweat into gauze, filter paper, or Macroduct coils; evaluating the amount collected either in weight (milligrams) or volume (microliters) and then measuring the sweat chloride concentration. Chloride provides the greatest discrimination in diagnosis compared with sodium, and is the preferred analyte.[40] For diagnostic purposes, the CFF requires laboratories to perform a quantitative analysis of sweat chloride following the techniques described in the NCCLS document C34-A2.[26,79] Chloride

concentration can be determined by either coulometric titration using a chloridometer or manual titration using mercuric nitrate. If a laboratory chooses to quantitate sweat chloride using an automated analyzer that employs an ISE, these methods must be systematically validated for accuracy, precision, and, particularly, the lower limit of the analytical measurement range. Instrumentation used for measuring sweat chloride concentration should be able to detect as low as 10 mmol/L on unadulterated sweat. Analysts should not attempt to boost the analytical sensitivity by adding extraneous chloride standard to patients' specimens.

Reference Intervals for Sweat Chloride

In the context of clinically significant findings, a sweat chloride >60 mmol/L is consistent with CF; concentrations between 40 and 60 mmol/L are considered borderline, and values <40 mmol/L are in general considered normal.[89] The functional upper limit for sweat chloride is 160 mmol/L.[79] Sweat chloride concentrations greater than 160 mmol/L are not physiologically possible and can represent specimen contamination or analytical error.[93] The chloride concentration should be interpreted in the context of the patient's clinical presentation, family history, and age. Some mutations of the CF gene are associated with borderline or normal sweat chloride concentrations.[89]

According to the CFF disease registry, 1.7% of CF patients had sweat chloride concentrations less than 60 mmol/L (mean of 45.1 mmol/L) and 0.5% had sweat chloride concentrations ≤40 mmol/L. These patients were diagnosed with CF on the basis of genotyping, nasal transepithelial potential difference studies, and clinical presentation.[28]

Decision Limits for Sweat Conductivity

There is a lack of consensus on the appropriate decision limit for sweat conductivity. The CFF states that a patient with a sweat conductivity ≥50 mmol/L should be referred for a confirmatory sweat chloride test, and Wescor recommends that conductivity values up to 60 mmol/L can be considered normal, and concentrations >80 mmol/L are positive for CF.[27,111]

Sweat Stimulation and Collection

Localized sweating is produced by iontophoresis of the cholinergic drug pilocarpine nitrate into an area of the skin. Iontophoresis uses a small electric current to deliver pilocarpine into the sweat glands from the positive electrode, and an electrolyte solution at the negative electrode completes the circuit. The current source should be battery powered and regularly inspected according to hospital guidelines by qualified personnel for voltage leak and current control.[79] After iontophoresis, sweat is collected onto preweighed gauze pads or filter paper or into Macroduct coils, using techniques to minimize evaporation and contamination. The Occupational Safety and Health Administration (OSHA) does not list sweat as a potentially infectious material unless it is visibly contaminated with blood.[82] However, laboratory personnel should practice the same universal precautions they would use with any other body fluid.

Because of transient increases in sweat electrolytes shortly after birth, patients should be at least 48 hours old before a sweat test is performed.[79] The patient should be physiologically and nutritionally stable, well hydrated, free of acute illness, and not receiving mineralocorticoids. The inner flexor surface of the forearm is the preferred site for sweat testing. Either the right or left arm is acceptable. If the arms are unavailable, sweat testing can be performed on the patient's upper leg. Never allow the current to cross the patient's chest. The skin should be free of cuts, rashes, and inflammation so as to prevent contamination of the sweat sample with serous fluid. For example, sweat testing should never be performed over an area of eczema.[14] The sweat test can be performed on a patient receiving intravenous fluid, as long as good contact between the skin and the electrode is possible, collection techniques do not interfere with venous flow, and the intravenous fluids do not contaminate the collection area. Iontophoresis should not be performed on a patient receiving oxygen by an open delivery system. Often such patients can temporarily receive oxygen by way of a face mask or nasal cannula, permitting sweat testing.

If sweat is collected onto gauze or filter paper, the electrodes are usually made of copper and are slightly smaller than the stimulation and collection area. Reagents include United States Pharmacopeia (USP) grade 0.2% to 0.5% pilocarpine nitrate solution, a dilute electrolyte solution, and type I distilled water. The composition of the electrolyte solution should be selected to prevent contamination with the sweat sample. A supply of gauze pads, low in electrolyte content, is necessary for cleansing and drying the skin. Before collection, the gauze or filter paper used for sweat collection should be placed into a weighing vial with a secure sealing lid, and the vial should be labeled and weighed using an analytical balance. To minimize contamination, the collection gauze or filter paper and the preweighed vial containing them should never be handled directly. The analyst should always use forceps or powder-free gloves. For a detailed procedure for stimulation and collection, refer to NCCLS document C34-A2.[79]

Alternatively, for sweat stimulation, the electrodes and current source can be integrated as in the Wescor Macroduct system, which uses gel reagents containing pilocarpine. The battery-powered iontophoresis system delivers a current of 1.5 mA for 5 minutes. Type I distilled water and gauze pads or tissues are necessary for cleaning the skin. Using this stimulation system, sweat is collected into a disposable microbore tubing coil collector. After sufficient sweat has been collected, it is transferred from the coil into a sealable microsample cup. When using the Macroduct collection system, the analyst should not touch or otherwise contaminate the concave collecting surface. For specific pro-

cedures using the Macroduct collection system, refer to the manufacturer's instructions.

To standardize and simplify the collection process, it is recommended that the size of the electrodes, reagent pads, and collection material be approximately the same. For example, using a 2 × 2-inch gauze or filter paper collection pad, the electrodes should be slightly smaller, about 1.5 × 1.5 inches, and the area of stimulation, represented by the size of reagent pads, should be the same size as the collection pads, 2 × 2 inches. When using the Wescor Macroduct stimulation system and Pilogel, sweat should be collected into the coils designed with the system.

Critical Issues Associated With Sweat Collection

The analyst must address several important issues when collecting sweat. These include adequate patient education, using appropriate stimulation and collection systems, preventing evaporation and contamination, collecting a sufficient sample, and minimizing skin reactions.

Patient Education

Sweat testing is one of the few clinical chemistry tests involving direct patient contact. Patients often have questions about the sweat test that their physicians may not have answered. Patient educational materials on sweat testing have been produced by the CFF in English and Spanish and include both written and video material.

Appropriate Stimulation and Collection Systems

Sweat should be collected in association with compatible stimulation equipment and not be hybridized. For example, laboratories using Wescor Pilogel iontophoresis should collect sweat only into the Macroduct coils and not onto gauze or filter paper.[79] Hybridizing the Wescor Pilogel iontophoresis system with gauze or filter paper collection can dramatically alter the minimum collection volume or weight required to ensure adequate sweat gland stimulation and affect the validity of the sweat electrolyte determination.

Evaporation and Contamination

Testing procedures should minimize the opportunity for evaporation and contamination of the sweat sample. Detailed instructions on minimizing evaporation and contamination can be found in the NCCLS sweat testing document.[79]

Specimen Weight and Collection Time

To have a valid sweat testing result, determination of and adherence to a minimum sweat weight or volume are critical. The requirement for a minimum amount is physiological, to ensure an appropriate sweat rate and sweat electrolyte concentration. It is independent of the instrumentation used to measure sweat electrolytes. Unfortunately, this is poorly understood, leading to false-positive and false-negative sweat test results, which have a significant implication for patient care. Sweat electrolyte concentration is related to sweat rate. At low sweat rates, sweat electrolyte concentration decreases and the opportunity for sample evaporation is increased.[39,79] To ensure a valid result, the average sweat rate should exceed 1 g/m^2/min. The minimum acceptable volume or weight depends on the size of the electrode and stimulation area, the type and size of collecting devices, and the length of time the sweat is collected.[79] If a laboratory deviates from standard parameters, the minimum acceptable sweat volume or weight will change. The stimulation and/or collection requirement applies to each site independently, so insufficient samples must not be pooled for analysis.

Applying the acceptable rate to the parameters described in the NCCLS document, the minimum acceptable sample for analysis from a single site using 2 × 2-inch gauze or filter paper for stimulation and collection is 75 mg of sweat collected within 30 minutes. Using the Macroduct system, the electrodes and stimulation area are smaller, and the minimum acceptable sample is 15 µL collected within 30 minutes. Sweat should be collected for only 30 minutes. If the collection time exceeds 30 minutes, the requirement for the amount of sweat necessary to ensure adequate stimulation would have to be increased. Extending the collection time can allow additional opportunity for sweat evaporation and practically does not significantly increase the sweat yield.[60]

Sufficient Sample Collection

Acquiring the minimum sample should not be a problem if the laboratorian follows both the procedure in the NCCLS document and the manufacturer's recommendations. On average, the percentage of insufficient samples should not exceed 5% for patients more than 3 months old.[26] The average amount of sweat collected on 2 × 2-inch gauze pads at one CF center is 282 mg and in Macroduct coils is 65 µL.[44,64] Insufficient sweat samples can be due to several factors, such as age, race, skin condition, and collection system. Although it may seem to be more difficult to obtain an adequate sweat sample in very young infants, studies have shown no statistically significant difference in the proportion of insufficient samples in patients younger than 6 weeks when compared with patients older than 6 weeks.[37] Collection systems vary with regard to insufficient samples, especially in young infants (e.g., there is a higher failure rate associated with collection using Macroduct coils than with collection onto gauze or filter paper).[44] If an adequate sweat sample is not obtained, the test can be repeated as soon as is practical because the rate of sweating can vary from day to day. To ensure adequate sweat production, the analyst should check that the reagents are within the expiration date and that the size of the stimulation area corresponds to the size of the collection surface.

Skin Reactions

Burns to the patient's skin after iontophoresis are extremely rare but can occur at either electrode. If the burn occurs at the site of pilocarpine stimulation, sweat should not be col-

lected. Pilocarpine urticaria associated with sweat testing is also rare but has been reported.[61]

To minimize the potential for burns, the analyst should:

1. Keep the electrode surfaces clean. Copper electrodes should be cleaned after every use with emery cloth to remove surface oxidation.
2. Attach the electrodes firmly. Maintain a wet interface with the skin during iontophoresis. When using liquid reagents on gauze or filter paper, ensure that they are thoroughly saturated. When using gel reagents, a drop of type I distilled water can be applied to the gel surface.
3. Prevent bare metal of the electrode from touching the skin. The gauze or filter paper pads should be slightly larger than the electrodes. When using gel reagents, do not use Pilogel disks that have a crack or structural defect in them.
4. Limit iontophoretic current. At the beginning of iontophoresis, slowly raise the current, and do not exceed 4.0 mA current.

Sources of Error in Sweat Testing

Unreliable methodology, technical errors, and errors in interpretation can all lead to erroneous sweat test results. Methods that do not quantitate sweat collected or do not have an established minimum sample volume or weight are subject to false-negative results because an adequate sweat rate cannot be ensured.

Other problems with sweat testing include errors of evaporation, contamination, and errors in dilution, instrument calibration, sample identification, and result reporting. These errors occur more frequently in institutions performing relatively few tests.[103] Laboratories with a low testing volume for sweat analysis should consider discontinuing the test and referring patients to accredited CF care centers for testing and evaluation. Interpretation errors with the sweat test include lack of knowledge about the laboratory method, failure to repeat borderline and positive results, failure to repeat negative test results when inconsistent with the clinical picture, and failure to repeat testing in patients diagnosed as CF who do not follow the expected clinical course. Malnutrition, dehydration, eczema, and rash can increase sweat electrolytes, whereas edema and the administration of mineralocorticoids can decrease sweat electrolytes.[89]

Sweat Testing Quality Assurance

High-quality sweat testing includes selecting appropriate methodology, having a sufficient testing volume to ensure familiarity with the test, and limiting the testing personnel to a small number of well-trained individuals. An effective quality assurance program for sweat analysis encompasses preanalytical, analytical, and postanalytical factors.

Preanalytical Quality Assurance

Physicians should be aware of the clinical spectrum of CF and appropriately order a sweat test on patients suspected of the disorder. Because of the significant preanalytical variation associated with sweat testing, duplicate testing from two body sites is recommended.[26] Most sweat chloride concentrations agree within 5 mmol/L on bilateral testing. Each laboratory should establish a required level of agreement for bilateral results. It has been suggested that when the sweat chloride concentration is less than 60 mmol/L the duplicate tests should agree within 10 mmol/L, and when the chloride concentration exceeds 60 mmol/L the tests should agree within 15 mmol/L.[79] Stimulation and collection procedures should minimize the opportunity for evaporation and contamination of the sweat sample. The patient's skin at the collection site should be free of inflammation or rash.

Analytical Quality Control

To monitor the accuracy and precision of the analytical process, two levels of controls should be performed every day when patient samples are analyzed. One control should reflect the concentration of sweat chloride concentration in a non-CF patient and the other control should reflect the concentration of sweat chloride found in a CF patient. The controls should be performed in parallel with patient samples and the results should fall within a predetermined range before patient results can be reported. Both short- and long-term quality control should be monitored.

An important part of a quality assurance plan includes the external validation of sweat analysis accuracy through participation in proficiency testing. The CAP offers a proficiency testing program consisting of six specimens per year. Participants receive feedback concerning their performance on these specimens relative to others in their peer group.

Postanalytical Quality Assurance

The results of the sweat test must be interpreted in light of the patient's clinical presentation by a physician knowledgeable about CF. There are several conditions other than CF that are associated with elevations in sweat electrolytes (Box 27-1). These conditions usually are distinguishable from CF based on the patient's clinical presentation.

BLOOD GASES AND pH

Clinical management of respiratory and metabolic disorders often depends on rapid, accurate measurements of oxygen and carbon dioxide in blood. Vigorous measures to support life in patients with cardiopulmonary impairment depend largely on assisted ventilation using mixtures of gases that are tailored in response to laboratory blood gas and acid-base results. Determination of blood gases also plays an important part in the detection of acid-base imbalance and in monitoring therapy. Modern instruments for blood gas determinations are simple to operate and, with meticulous maintenance and quality control, are capable of rapid turnaround of very reliable laboratory data. physiology of blood gases in relation to respiration and acid-base disorders are discussed in detail in Chapter 46.

The recommended nomenclature in this area of analysis has been finalized by the NCCLS,[77] but because alternative nomenclatures exist[51] and are in common use, some of these are also summarized in Box 27-2.

Behavior of Gases

Determination of gas pressures in expired air or blood depends on the application of certain physical principles (Table 27-4). The partial pressure of a gas dissolved in blood is by definition equal to the partial pressure of the gas in an imaginary ideal gas phase in equilibrium with the blood. At equilibrium, the partial pressure (tension) of a gas is the same in erythrocytes and plasma, so that the partial pressure of a gas is the same in whole blood and plasma. The partial pressure of a gas in a gas mixture is defined as the substance fraction of gas (mole fraction) times the total pressure. The tension of a gas in a liquid is, in fact, a measure of the chemical activity of the gas in the liquid. In the physicochemical literature, it is called the *fugacity.*

Various spaces where gases are present include the ambient environment (room air), the bronchial tree and alveoli of the patient, and the measuring chamber of a laboratory instrument. In all these spaces, atmospheric (baro-

BOX 27-2 Conversion Factors, Prefixes, Symbols, and Descriptors Used in Discussions of Gases Measured in Blood and Expired Air*[67,77]

Conversion Factors

1 mm Hg = 0.133 kPa
1 kPa = 7.5 mm Hg
kPa: 1 kilopascal = 1000 pascal. The pascal is the SI derived unit of pressure; it equals 1 Newton/m^2 (see also Chapter 1)

General Prefixes

P: partial pressure or tension
Usage: PO_2, PCO_2, PH_2O
Alternative: pO_2
S: saturation fraction
Usage: SO_2
Alternative: sO_2
c: substance concentration
Usage: ctO_2 for concentration of total O_2
Usage: $ctCO_2$ for concentration of total CO_2
Usage: $cHCO_3^-$ for concentration of bicarbonate
d: dissolved gas, used with substance concentration (*c*)
t: total, used with substance concentration (*c*), thus $ctCO_2 = HCO_3^- + cdCO_2$
Specimen origin is indicated by lower case letters. Whole blood and plasma are distinguished by capitals.

a: arterial	B: blood
v: venous	P: plasma
c: capillary	

Usage: PO_2(aB), for partial pressure of O_2 in arterial blood

Prefixes Associated with External Respiration

V: volume of air or blood (unit, L)
$\dot{V}$: volume rate (unit, L/min)
F: substance fraction, also called mole fraction
E: expired air
I: inspired air
A: alveolar air
Usage: $\dot{V}$(A) means alveolar ventilation; and $\dot{V}$(B) cardiac output; FO_2(I) fraction of O_2 in inspired air; PO_2(A) partial pressure of O_2 in alveolar air; and PCO_2(E) partial pressure of CO_2 in expired air.

Other Descriptors

BTPS: *B*ody *T*emperature (37 °C or 310.16 K) and ambient *P*ressure, fully *S*aturated (PH_2O = 47 mm Hg or 6.25 kPa)
STPD: *S*tandard *T*emperature (0 °C or 273.16 K) and standard *P*ressure (760 mm Hg or 101.08 kPa) of *D*ry gas
Amb: ambient atmosphere (unit is atm, atmosphere)
B: barometric (atmospheric)
BTPS: Usage: *P*(amb), *P*(Amb)
SVP: *S*aturated *V*apor *P*ressure, the vapor pressure of water. SVP_T means SVP at a specified temperature, e.g., $SVP_{37\,°C}$ = 47 mm Hg; PH_2O(saturated)
ATPS: *A*mbient *T*emperature and *P*ressure, *S*aturated with water vapor

*This list is not complete, but is presented to facilitate interpretation of terms used in the text and to illustrate various forms that may be encountered in the literature.

TABLE 27-4 Physical Principles Applied in Blood Gas Measurements

Boyle's law: The volume of an ideal gas at a constant temperature varies inversely with the pressure exerted to contain it.	$V \propto 1/P$
Charles' (Gay-Lussac's) law: The volume of an ideal gas at a constant pressure varies directly with its absolute temperature.	$V \propto T$
Avogadro's hypothesis: Equal volumes of different ideal gases at the same temperature and pressure contain the same number of molecules.	$n_i/V_i = n_j/V_j$
Dalton's law: The total pressure exerted by a mixture of ideal gases is the sum of the partial pressures of each of the gases in the mixture.	$P = \Sigma P_i$
Henry's law: The amount of a sparingly soluble gas dissolved in a liquid is proportional to the partial pressure of the gas over the liquid.	$c = \alpha \times P$

metric) pressure, P(Amb), is the prevailing pressure, and partial pressures of each of the gases present in these spaces must add up to the value of P(Amb), which will vary with altitude and barometric pressure. Scientific convention reduces measurements of gas volumes made at P(Amb) to standard temperature (0 °C or 273.16 K) and pressure (760 mm Hg or 101.325 kPa) for dry gas (STPD) to make experimental data transferable. However, in blood gas work, the standard is that measurements of partial pressure are always made at body temperature (usually 37 °C), at P(Amb), and in the presence of saturated water vapor (PH_2O = 47 mm Hg). Use of this BTPS convention (see Box 27-2) has the following practical effects:

1. It relates laboratory data for blood gases strictly to the geographical location of the patient, so that reference intervals become altitude dependent.
2. It assumes a standard body temperature of 37 °C and that the measuring device also holds the sample of blood at exactly 37 °C. This assumption requires special concern for thermal stability of the instrument. Just as important, it implies that in circumstances such as *imposed* hypothermia, when a patient's temperature is not 37 °C, blood gas values determined at 37 °C might need to be corrected to the actual body temperature to obtain an estimate of blood gas partial pressures in the patient. Temperature corrections are addressed later in this section.
3. It recognizes that the partial pressures of measured gases in the blood coexist with a constant and standard saturated vapor pressure (SVP), which is identical for both the calibration conditions of the instrument and measurement conditions of the blood sample.

Boyle's and Charles' laws and Avogadro's hypothesis are combined in what is called the *general gas equation:*

$$P = (nRT)/V$$

where

P = pressure in units of millimeters of mercury (mm Hg)
n = Hg or kilopascals (kPa)
V = volume in liters in which an ideal gas is contained
T = temperature in degrees kelvin (0 °C = 273.16 K)
n = number of moles of gas, and
R = gas constant

The SI unit of P is the pascal (Pa). However, millimeters of mercury (also called *torr*) has continued to remain popular (see Box 27-2 for conversion factors). Use of SI units does have a practical advantage in that 1 atm almost equals 100 kPa (1 atm = 101.325 kPa). Partial pressures expressed in kilopascals are therefore very close estimates of percentages of the gases in the mixture at 1 atm. Pressure, P (or p), may mean either total pressure, as in the expression P(Amb) for the mixture of gases in ambient air, or partial pressure in blood, as in PO_2(aB). Numerical value and units of R differ depending on the units used for P, so that:

$$R = 62.36\ \text{mm Hg} \times \text{L} \times {}^{\circ}\text{K}^{-1} \times \text{mol}^{-1}$$

or

$$R = 8.31\ \text{kPa} \times \text{L} \times {}^{\circ}\text{K}^{-1} \times \text{mol}^{-1}$$

After rearranging terms and evaluating n as 1 mol and P as 760 mm Hg, the volume of 1 mol of a pure ideal gas at 0 °C (no water vapor) is 22.4 L. The general gas equation is the justification for accepting partial pressures of gases in blood as estimators of their concentrations. However, PO_2 is related only to the concentration of dissolved O_2 (cdO_2) in the blood and PCO_2 to the concentration of dissolved CO_2 ($cdCO_2$) in the blood (see Henry's law, Table 27-4.) In fact, the total concentration of O_2 in blood ctO_2 is the sum of concentrations of dissolved O_2 and of O_2 bound to hemoglobin, with dO_2 being a small component of tO_2 (see Hemoglobin Saturation section later in this chapter). The total concentration of CO_2 ($ctCO_2$) is defined operationally as the sum of concentrations of dissolved CO_2, carbonic acid, HCO_3^-, undissociated bicarbonate, and carbonate ion.

Dalton's law (see Table 27-4) may be written for room air as

$$P(\text{Amb}) = PO_2 + PCO_2 + PN_2 + PH_2O + PX$$

where PX is that of any other gas in the air sample.

However, for gases in solution, Dalton's law does not apply. That is, the sum of partial pressures of all the dissolved gases may be lower than, equal to, or higher than the measured pressure of the solution. For instance, if the sum of gas tensions is significantly higher than the pressure of the solution, bubbles may form, as they can in the blood of divers surfacing from the deep (giving rise to a condition known as "the bends") or in a cold blood sample being warmed for analysis. Dalton's law of partial pressures remains important, however, for calibration and control of the measuring devices.

Consider a calibrator gas certified to contain 15% O_2 (L/L or mol/mol) and 5% CO_2, the remainder being N_2. The mole fractions (or *F*) of the gases in the dry mixture are 0.15, 0.05, and 0.80, respectively. This mixture, after saturation with water vapor at 37 °C (to mimic a patient's blood or alveolar air), is introduced into a blood gas instrument's measuring chamber (held at 37 °C to mimic a patient's body temperature) for the purpose of calibrating the instrument for subsequent measurements of gases in patients' samples. If the local barometric pressure, *P*(Amb), on this occasion is 747 mm Hg, then the humidified calibrator gas is present in the chamber at ambient, barometric pressure, such that

$$P(\text{Amb}) = 747\ \text{mm Hg} = PO_2 + PCO_2 + PN_2 + PH_2O$$

To set the instrument to the PO_2 and PCO_2 of the calibrator gas, we must first account for PH_2O at 37 °C, which is equal to SVP of water, 47 mm Hg. Therefore

$$P(\text{Amb}) - PH_2O = PO_2 + PCO_2 + PN_2$$
$$= 747 - 47 = 700\ \text{mm Hg}$$

If P(Amb) corrected for PH_2O represents the sum of partial pressures for the dry gases whose mole fractions we know, we can calculate the exact PO_2 and PCO_2 values for the calibrator gas, under the circumstances of measurement, and then enter these calibrator values into the instrument:

$$PO_2 = 700 \times 0.15 = 105\ \text{mm Hg}$$
$$PCO_2 = 700 \times 0.05 = 35\ \text{mm Hg}$$

The law of partial pressure is also applied in defining gas mixtures used to determine $PO_2(0.5)$ or P_{50} and other derived quantities and to control instrumentation with tonometered samples.

Henry's law predicts the amount of dissolved gas in a liquid in contact with a gaseous phase (see Table 27-4). The concentration (mol/L) of free dissolved gas (dG) in blood (B) is calculated:

$$c\text{dG(B)} = \alpha\text{G(B)} \times P\text{G(B)}$$

where αG(B) is the coefficient of solubility for the gas in blood at 37 °C.

The coefficient for O_2 in blood, αO_2, is 0.00140 (mol/L)/mm Hg (the corresponding coefficient for the volume-volume relationship is 31 µL/L/mm Hg). Therefore when arterial PO_2 is normal (100 mm Hg) the concentration of dissolved O_2 in arterial blood, cdO_2, is 0.140 mmol/L, which is a very small proportion of the ctO_2 content in blood (~9 mmol/L), the bulk of which is O_2 bound by hemoglobin. Increasing the O_2 fraction of inspired air to 100% or increasing the pressure of inspired air, as in a hyperbaric chamber, forces more O_2 into a solution. In therapy with pure O_2, when PO_2 may rise to 640 mm Hg, the cdO_2 could be as high as 0.9 mmol/L. In hyperbaric treatment, an arterial PO_2 of 2500 mm Hg (~3.2 atm) is equivalent to cdO_2 of 3.5 mmol/L. Prediction of concentrations of cdO_2 in these therapies is useful because tissue oxygenation by dissolved O_2 becomes increasingly important when hemoglobin-mediated O_2 delivery is impaired.

The $cdCO_2$ can be calculated in the same way: αCO_2 at 37 °C in plasma = 0.0306 mmol/L/mm Hg. Thus at a PCO_2 of 40 mm Hg, the $cdCO_2 = 40 \times 0.0306 = 1.224$ mmol/L. In the determination of blood gases, PCO_2 is determined along with blood pH. As will be subsequently explained, these two parameters in conjunction with the Henderson-Hasselbalch equation permit the calculation of HCO_3^-, as follows:

$$\log c\text{HCO}_3^- = \text{pH} - pK' + \log[PCO_2 \times \alpha CO_2(\text{P})]$$

The antilog is then taken to derive $cHCO_3^-$.

Application of the Henderson-Hasselbalch Equation in Blood Gas Measurements

Carbon dioxide and water react to form carbonic acid, which in turn dissociates to hydrogen ions and HCO_3^-.

$$CO_2 + H_2O \underset{}{\overset{K_{\text{hydration}}}{\rightleftharpoons}} H_2CO_3 \overset{K_{\text{dissociation}}}{\rightleftharpoons} H^{\oplus} + HCO_3^{\ominus}$$

Thus the total concentration of CO_2 ($ctCO_2$), the concentration of bicarbonate ($cHCO_3^-$), the concentration of dissolved CO_2 ($cdCO_2$), and H^+ ion concentration (cH^+) are interrelated. The constant *K* for the hydration reaction is 2.29×10^{-3} ($pK = 2.64$ at 37 °C), whereas the constant *K* for the dissociation of carbonic acid is 2.04×10^{-4} ($pK = 3.69$).

In the classical formulation, Henderson (1908), using concentrations for bicarbonate, CO_2, and H^+ and assuming the concentration of water to be constant, combined these two reactions and incorporated the constant K' with a value of 4.68×10^{-7}, and thus a pK' of 6.33 at 37 °C:

$$K' = cH^+ \times cHCO_3^- / cdCO_2$$

The concentration of dissolved CO_2 *includes* the small amount of undissociated (dissolved) carbonic acid. It can be expressed as $cdCO_2 = \alpha \times PCO_2$, where α is the solubility coefficient for CO_2. $cHCO_3^-$ then represents $ctCO_2$ minus $cdCO_2$, which includes carbonic acid. The "bicarbonate" concentration by this definition includes undissociated sodium bicarbonate, carbonate ($NaCO_3$) and carbamate (carbamino-CO_2; $RCNHCOO^-$), which are present in exceedingly small amounts in plasma.

If the Henderson equation is rearranged and $cdCO_2$ is replaced by $\alpha \times PCO_2$, the following equation results:

$$cH^+ = K' \times \alpha \times PCO_2 / cHCO_3^-$$

In 1916 Hasselbalch showed that a logarithmic transformation of the equation was a more useful form, and used the symbols pH (= $-\log cH^+$) and pK' (= $-\log K'$). pH is defined as the negative log of the *activity* of H^+ (aH^+), which is the entity actually measured with pH meters. The resulting Henderson-Hasselbalch equation becomes

$$pH = pK' + \log[cHCO_3^- / (\alpha \times PCO_2)]$$

or

$$pH = pK' + \log\{[ctCO_2 - (\alpha \times PCO_2)]/(\alpha \times PCO_2)\}$$

K' is the apparent, overall (combined) dissociation constant for carbonic acid. It is *apparent* because concentrations are used rather than activities and *overall* because both the $cdCO_2$ and the concentration of carbonic acid are used. K' depends not only on the temperature but also on the ionic strength of the solution.

For blood at 37 °C, the normal mean value is pK'(P) = 6.103, with a normal biological standard deviation (SD) of about ±0.0015, mainly caused by variations in ionic strength. The solubility coefficient for CO_2 gas, α, also varies with the composition of the solution. For pure water at 37 °C, the solubility coefficient $\alpha = 0.0329\,mmol \times L^{-1} \times mm\,Hg^{-1}$, and for normal plasma at 37 °C it is $0.0306\,mmol \times L^{-1} \times mm\,Hg^{-1}$, with a biological SD of about $\pm 0.0003\,mmol \times L^{-1} \times mm\,Hg^{-1}$.

Inserting pK' and α for normal plasma at 37 °C, the Henderson-Hasselbalch equation takes the following form:

$$pH = 6.103 + \log \frac{cHCO_3^-}{0.0306 \times PCO_2}$$

or

$$pH = 6.103 + \log \frac{ctCO_2 - 0.0306 \times PCO_2}{0.0306 \times PCO_2}$$

where PCO_2 is measured in millimeters of mercury and $cHCO_3^-$ and $ctCO_2$ are measured in millimoles per liter. Taking the antilogarithm, combining the constants, and expressing $[H^+]$ in nmol/L, the equation becomes

$$cH^+ = 24.1 \times \frac{PCO_2}{cHCO_3^-}$$

If normal values are substituted in the equation,

$$cH^+ = 24.1 \times \frac{40}{25.4}\,nmol/L = 38.0\,nmol/L$$

Clearly, by measuring any two of the four parameters, PCO_2 or $cdCO_2$, pH, $ctCO_2$, or $cHCO_3^-$, and using the Henderson-Hasselbalch equation with the above appropriate values for pK' and α, the other two parameters may be calculated. Although used as constants, these values must be recognized as means and susceptible to biological variation. Changes in ionic strength of ±20% cause changes in pK' between 6.08 and 6.12. Variations in pK' of plasma also occur with temperature (pK will decrease 0.0026 per 1 °C increase and decrease slightly with increasing pH). For most clinical purposes, these variations of pK' can be ignored. However, in pathological cases with markedly deviant ionic strength, the change in pK' may be significant. The value of α is affected by the presence of increased salts or proteins in solution (value decreases) or lipids (value increases). For instance, in lipemic plasma, the value of α may be 0.033 or even higher. Thus parameters calculated on the assumption that pK' and α are invariant may have significant error under certain pathological circumstances, and several authors suggest caution in using values calculated from blood gas analyzers in extremely ill patients and in children.[75,87] For instance, one study showed that in 17 of 51 adult intensive care unit patients, the calculated and measured tCO_2 values differed by >10%,[75] whereas another showed differences >20% in 27 of 107 pediatric intensive care unit patients.[87] Nevertheless, with both pH and PCO_2 measured electrochemically, $cHCO_3^-$, $cdCO_2$, and $ctCO_2$ are routinely calculated by algorithms in the microprocessors of most blood gas instruments. One advantage of such a calculated value is that it essentially reflects the *activity* of HCO_3^- (i.e., bicarbonate concentration is reported as if measured with an ISE) in the *water* phase of plasma, and thus it is not affected by the electrolyte exclusion effects, as other nondirect measurements of HCO_3^- may be.

Oxygen in Blood

The total O_2 content (ctO_2) of a blood sample is the sum of the concentrations of hemoglobin-bound O_2 and of dissolved O_2. At a blood ctO_2 of 9 mmol/L, the cdO_2 is only approximately 0.14 mmol/L, and the rest of the O_2 is associated with hemoglobin as oxyhemoglobin (O_2Hb). The O_2Hb is defined as erythrocyte hemoglobin with O_2 reversibly bound to Fe^{2+} of its heme group. Each mole of hemoglobin-Fe^{2+} binds 1 mol of O_2. In erythrocytes, hemoglobin exists as a tetramer (64,456 g/mol), but when expressing Hb concentration in moles per liter, it is reported as the concentration of monomer (16,114 g/mol). Thus 1 L of blood with a normal hemoglobin concentration (cHb) of 9.3 mmol/L (~15 g/dL or 150 g/L) carries 9.3 mmol of O_2 at STPD if all hemoglobin is in the form of O_2Hb.

Thus 1 g of hemoglobin is capable of binding 1.39 mL (0.062 mmol) of O_2 at STPD. This value is referred to as the specific O_2 binding capacity of hemoglobin A (Hb A, the normal adult gene product). Hb A reversibly binds O_2 at its heme moiety and also binds biological effectors at other allosteric sites on the molecule. Methemoglobin (MetHb), carboxyhemoglobin (COHb), sulfhemoglobin (SulfHb), and cyanmethemoglobin are forms of hemoglobin that are not capable of reversible binding of O_2 caused by chemical alterations of the heme moiety (see Chapter 31). These

chemically altered hemoglobins are collectively termed *dyshemoglobins.* Another group of abnormal hemoglobins have genetically determined changes in their amino acid sequence that can alter the allosteric binding properties of the molecule and thus affect O_2 affinity. These hemoglobins are collectively referred to as hemoglobin variants or hemoglobinopathies. More than 500 hemoglobin variants have been described,[7,17] with sickle cell hemoglobin (Hb S) as just one example.

Uptake of O_2 by the blood in the lungs is governed primarily by the PO_2 of alveolar air and by the ability of O_2 to diffuse freely across the alveolar membrane into the blood. At the PO_2 normally present in alveolar air (~102 mm Hg) and with a normal membrane and normal hemoglobin A, more than 95% of hemoglobin will bind O_2. At a $PO_2 > 110$ mm Hg, more than 98% of normal hemoglobin A binds O_2. When all hemoglobin is saturated with O_2, further increase in the PO_2 of alveolar air simply increases the concentration of dO_2 in the arterial blood.

Delivery of O_2 by the blood to the tissue is governed by the large gradient between PO_2 of the arterial blood and that of the tissue cells, and by the dissociation of O_2Hb in the erythrocytes at the lower PO_2 of the blood–tissue cell interface.

Three properties of the arterial blood are essential to ensure adequate O_2 delivery to the tissue:

1. Arterial PO_2 must be sufficiently high (~90 mm Hg) to create a diffusion gradient from the arterial blood to the tissue cells. Low arterial PO_2 (hypoxemia) results in tissue hypoxia (O_2 starvation).
2. The O_2-binding capacity of the blood must be normal (i.e., the concentration of hemoglobin capable of binding and releasing O_2 must be normal). Decreased Hb concentration may cause so-called anemic hypoxia.
3. The hemoglobin must be able to bind O_2 in the lungs yet release it at the tissue. In other words, the affinity of hemoglobin for O_2 must be normal. Too great an affinity of hemoglobin for O_2 may cause "affinity-based" tissue hypoxia, in which O_2 is not released at the capillary-tissue interface (see later in this chapter).

The PO_2 at the venous end of the capillaries should stay around 38 mm Hg, and thus the normal arteriovenous difference in PO_2 is 50 to 60 mm Hg. This corresponds to a normal delivery of 2.3 mmol of O_2 to the tissue per liter of blood.

Hemoglobin Oxygen Saturation

Before discussing the factors that affect Hb affinity for O_2, it is important to define the concept of hemoglobin oxygen saturation (SO_2):

$$SO_2 = \frac{\text{Oxygen content}}{\text{Oxygen capacity}}$$

This is the fraction (percentage) of the functional hemoglobin that is saturated with oxygen and is essentially an indirect means of estimating the PO_2. However, at least three different approaches exist for determining oxygen "saturation," and although each is distinct, they are often used interchangeably to determine "oxygen saturation." These three terms, hemoglobin oxygen saturation (SO_2), fractional oxyhemoglobin (FO_2Hb), and an estimated oxygen saturation (O_2Sat), have distinct definitions set by the NCCLS.[77] The ambiguous use of these three terms is due to the fact that in healthy subjects with normal amounts of normal hemoglobin, the values for all three entities are very similar. However, the assumptions made for normal, healthy subjects can lead to erroneous conclusions in seriously ill patients and those with dyshemoglobins or hemoglobin variants when these values are used interchangeably.

Spectrophotometric methods are used to determine O_2Hb and HHb,[72] and SO_2 is calculated according to

$$SO_2 = \frac{cO_2Hb}{cO_2Hb + cHHb}$$

where cO_2Hb is the concentration of oxyhemoglobin, cHHb the concentration of deoxyhemoglobin, and the sum of oxyhemoglobin and deoxyhemoglobin represents all hemoglobin capable of reversibly binding O_2. SO_2 is usually expressed as a percent in the United States, but may also be expressed as a decimal fraction of 1.00.

SO_2 is most often determined by simple pulse oximetry, a spectrophotometric approach that can determine oxyhemoglobin and reduced hemoglobin (HHB) but not COHb, MetHb, or SulfHb. These devices measure absorbance at 660 and 940 nm for which O_2Hb and HHb have unique absorbance patterns. These are usually bedside monitors used for monitoring HbO_2 saturation and serve this purpose extremely well. However, use of SO_2 in the initial evaluation of a patient with dyshemoglobins or other abnormal hemoglobins can be very misleading. For instance, in a comatose patient with 15% COHb, the SO_2 by simple pulse oximetry might read 0.95, whereas the fraction of oxyhemoglobin would in reality only be 0.80. Thus it seems reasonable to assess for the presence of dyshemoglobins before using SO_2 for clinical purposes. The reference interval for SO_2 from healthy adults is 0.94 to 0.98 (94% to 98%).[101]

Another expression of oxygen "saturation" is the fractional oxyhemoglobin (FO_2Hb), which is calculated as:

$$FO_2Hb = \frac{cO_2Hb}{ctHb}$$

where the concentration of total hemoglobin ctHb equals the sum of O_2Hb, HHb, COHb, MetHb, and SulfHb. This value requires determination of all hemoglobin species and can be performed on a co-oximeter or on some modern blood gas analyzers, such as those from Instrumentation Laboratories or Radiometer. These instruments prepare a hemolysate from whole blood by sonication and by spectrophotometer determine the total amount of hemoglobin and the percent of each of the aforementioned species. This is accomplished by using monochromatic light at 6 to 128 fixed wavelengths between 535 and 670 nm and measuring absorbance at each

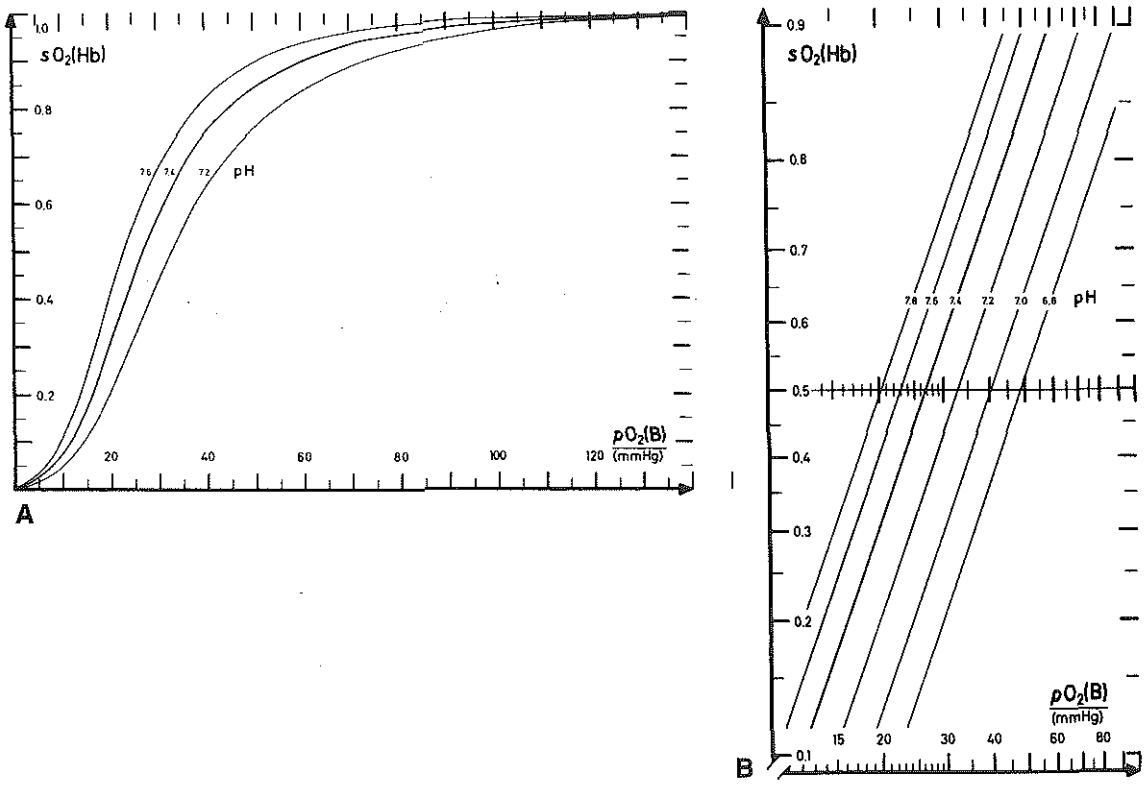
of the wavelengths. Newer co-oximeters from Bayer Diagnostics and AVL use a diode array and the Radiometer ABL 700 series uses 128 wavelengths. Because each species of hemoglobin has its own absorbance pattern, a microcomputer can calculate the percent of each one. The reference interval for FO_2Hb is 0.90 to 0.95 (90% to 95%).

The microprocessors of blood gas instruments sometimes estimate the oxygen saturation (SO_2) from measured pH, PO_2, and hemoglobin with the use of empirical equations.[99] If used at all, this value should be clearly referred to as an estimated SO_2, but it is frequently reported as and referred to as "O_2Sat." Calculated values such as "O_2Sat" should be interpreted with reservation because the algorithmic approach assumes normal O_2 affinity of the hemoglobin, normal 2,3-diphosphoglycerol (2,3-DPG) concentrations, and the absence of dyshemoglobins. Such calculated estimates have been found to vary as much as 6% saturation from measured values.[90] Because of this, the NCCLS has discouraged the use of estimated values.[77]

Decreases in arterial FO_2Hb indicate either a low arterial PO_2 or an impaired ability of hemoglobin to bind O_2. The amount of O_2 that the blood can carry is determined by three major factors: the PO_2, which reflects how much O_2 is dissolved in the blood; the amount of normal (effective) hemoglobin available in erythrocytes; and the affinity of the available hemoglobin for O_2. Decreases in PO_2 indicate a reduced ability of O_2 to diffuse from alveolar air into the blood. This can be due either to hypoventilation or to increased venoarterial shunting that is secondary to cardiac or pulmonary insufficiency. In either case, the result is a right-to-left shunting of blood that has not reached equilibrium with the alveolar air. This results in a decreased PO_2 and an increased PCO_2. Decreases in the concentration of total hemoglobin can result from a decreased number of erythrocytes that contain a normal concentration of hemoglobin (normochromic anemia) or a decreased mean cell concentration of hemoglobin in the erythrocytes (hypochromic anemia). Decreased FO_2Hb hemoglobin can also occur as a result of poisonings that convert part of the hemoglobin into the species COHb, MetHb, SulfHb, or cyanmethemoglobin, which cannot properly bind or exchange O_2. Clinically, it is important to distinguish between arterial hypoxemia (decreased arterial PO_2 and decreased SO_2 or FO_2Hb because of decreased availability of O_2) and cyanosis (decreased FO_2Hb because of abnormally high concentrations of reduced hemoglobin or chemically altered hemoglobin incapable of carrying O_2). Note that in the cyanosis setting, measurement of SO_2 or an estimated SO_2 ("O_2Sat") could be normal if the cyanosis is due to the presence of metHb or COHb.

The oxygen concentration of blood (ctO_2) is the sum of O_2 bound to hemoglobin and cdO_2. Originally, ctO_2 was determined by blood collected anaerobically and treated with ferricyanide reagent to liberate O_2 from hemoglobin under negative pressure to release all free O_2 from solution. The oxygen binding capacity was the amount of O_2 in the same sample determined in the same manner after the blood had been equilibrated with a gas mixture sufficiently rich in O_2 to saturate the blood with O_2. Blood gas analyzers determine ctO_2 by the following calculation[77]:

$$ctO_2(mL/dL) = FO_2Hb \times bO_2 \times ctHb(g/dL) + (\alpha O_2) \times (PO_2)$$



where bO_2 equals 1.39 mL/g and αO_2, the solubility coefficient of O_2 at 37 °C and STPD, equals 0.0031 (mL/dL)/mm Hg = 0.00140 (mmol/L)/mm Hg. Note that this calculation is based on FO_2Hb and $ctHb$. If SO_2 is used, it is necessary to use the effective hemoglobin concentration (i.e., to subtract the concentration of any dyshemoglobins present from the concentration of $ctHb$). Thus on initial patient presentation, determination of any dyshemoglobins may be necessary to obtain an accurate value for ctO_2 for its use in subsequent calculations.

Hemoglobin-Oxygen Dissociation

The degree of association or dissociation of O_2 with hemoglobin is determined by PO_2 and the affinity of hemoglobin for O_2. When the SO_2 of blood is determined over a range of PO_2 and plotted against PO_2, a sigmoidal curve called the O_2 dissociation curve is obtained. The *shape* of the curve arises from the increasing efficiency with which HHb molecules bind more O_2 once some O_2 has been bound ("cooperativity"; see also Chapter 31). The *location* of the curve relative to the PO_2 required to achieve a particular concentration of SO_2 in the blood is a function of the affinity of the hemoglobin for O_2.

The affinity of hemoglobin for O_2 depends on five factors: temperature, pH, PCO_2, concentration of 2,3-DPG, and the presence of minor hemoglobins, such as COHb and metHb. Dissociation of O_2 in relation to 2,3-DPG concentration and abnormal hemoglobin proteins, such as fetal hemoglobin (Hb F), thalassemias, and other hemoglobinopathies, is discussed in Chapter 31. Note that Figure 46-7 illustrates the effect of different concentrations of 2,3-DPG on the SO_2-PO_2 relationship. This chapter describes the effects of temperature, pH, and PCO_2 on dissociation behavior.

The graph in Figure 27-3 illustrates the effect of plasma pH on the O_2 dissociation curve (the Bohr effect). Similar graphs can be made for variations of PCO_2, 2,3-DPG, and temperature. The shifting locations of the curves are described in the third column of the chart in Figure 27-3, with increasing affinity for O_2 shifting the curve to the left. These sigmoidal curves, however, are difficult to use when quantitative estimates of the amount of shift are desired, when calculating the PO_2 at which 50% of Hb is binding O_2 (P_{50}). The Hill logit-log transform (illustrated as the Hill plot, Figure 27-3, *B*) converts the curvilinear dissociation function into a linear function. The slope of the linear function, called the *Hill slope*, is essentially constant at 2.7 for an SO_2 between 40% and 80%.

Deviation from Standard Conditions	Shift in Dissociation Curve	Affinity of Hemoglobin for O_2	Coefficient of Change*
pH(P) > 7.4	←	↑	$\frac{\Delta \log PO_2}{\Delta pH(P)} = -0.46$
pH(P) < 7.4	→	↓	
Temperature			
>37 °C	→	↓	$\frac{\Delta \log PO_2}{\Delta T} = +0.024\ K^{-1}$
<37 °C	←	↑	
PCO_2 > 40 mm Hg	→	↓	$\frac{\Delta \log PO_2}{\Delta \log PCO_2} = +0.02$
PCO_2 < 40 mm Hg	←	↑	
*c*DPG(E)			
>normal	→	↓	$\frac{\Delta \log PO_2}{\Delta(c\text{DPG(E)}/c^*)} = +0.04$
<normal	←	↑	

Figure 27-3 A, Oxygen dissociation curves for human blood with different plasma pH, but constant PCO_2 of 40 mm Hg, a 2,3-diphosphoglycerol concentration in erythrocytes of 5.0 mmol/L, and temperature at 37 °C. **B,** A Hill plot. Conditions are the same as in **A.** *DPG,* 2,3-diphosphoglycerol.

*The coefficients given in this chart are the basis for the correction of measured PO_2; their application to P_{50} correction is discussed in the text contained on the Evolve site that accompanies this book. The effect of pH(P) to shift the dissociation curve is called the *Bohr effect*; the coefficient above for $\Delta \log PO_2/\Delta pH(P)$ applies to conditions when the PCO_2 is 40 mm Hg and changes in pH(P) are due to changes in concentrations of noncarbonic acids and bases. If, however, the changes in pH(P) are being caused by changes in PCO_2, then the absolute value of the coefficient is greater, i.e., $\Delta \log PO_2/\Delta pH(P) = -0.49$. The coefficients for the Bohr effect are specified for PO_2 of whole blood but use the pH of plasma, pH(P). The coefficient for DPG effect is based on the DPG concentration in the erythrocytes *c*DPG(E).

$c^* = 1$ mmol/L.

The linear transforms of the dissociation curves have allowed linear coefficients of change (fourth column of the chart in the legend to Figure 27-3) to be determined for each of the factors that shift dissociation curves, and hence the lines on the Hill plot. These coefficients find application, singly or in combination, for correcting measured PO_2 or calculated P_{50} for the effects of different temperature, PCO_2, pH, and 2,3-DPG concentrations.

Determination of P_{50}

P_{50} is defined as the PO_2 for a given blood sample at which the hemoglobin of the blood is half saturated with O_2. The measured value of P_{50} differs from the standard value of P_{50} by some amount determined by the extent that pH differs from 7.40, PCO_2 differs from 40 mm Hg, temperature differs from 37 °C, and 2,3-DPG differs from 5.0 mmol/L. The value of P_{50} therefore becomes a measure of change of the hemoglobin affinity because of the factors that affect it. A procedure for determining P_{50} is available on the Evolve site that accompanies this book.[7,56,91,95,101] The procedure uses the principle that:

$$\log P_{50} = \log PO_2 - \text{logit}\, SO_2/2.7$$

where $\text{logit}\, SO_2 = \log[SO_2/(1 - SO_2)]$ and 2.7 is the Hill slope.

The P_{50} reference intervals for adults, measured at 37 °C and corrected to pH(P) of 7.4, are 25 to 29 mm Hg. For newborn infants, the interval is 18 to 24 mm Hg because of the presence of fetal Hb (Hb F).

Clinical Significance

Increased values for P_{50} indicate displacement of the O_2 dissociation curve to the right (i.e., a decreased affinity of the hemoglobin for O_2). The chief causes are hyperthermia, acidemia, hypercapnia, high concentrations of 2,3-DPG, or presence of a hemoglobin variant with decreased O_2 affinity. The physiological effects of decreased affinity of hemoglobin are small. In general, the affinity is still sufficient to allow the hemoglobin to bind adequate amounts of O_2 in the lungs. Low affinity facilitates dissociation of O_2Hb at the peripheral tissue cell. Indeed, in anemia, low affinity (as a result of increases in 2,3-DPG) is a desirable compensatory mechanism.

Low values for P_{50} signify displacement of the O_2 dissociation curve to the left (i.e., increased affinity of hemoglobin). The main causes are hypothermia, acute alkalemia, hypocapnia, low concentration of 2,3-DPG, increased COHb and MetHb, or a hemoglobin variant. Decreases of 2,3-DPG are commonly observed in acid states that have persisted for more than a few hours. The initial increase in P_{50} caused by the acidemia is gradually compensated for by a decrease in 2,3-DPG so that P_{50} then falls to lower than normal values. The physiological consequence of increased affinity of hemoglobin for O_2 is less efficient dissociation of O_2Hb at the peripheral tissue and lower tissue PO_2.

TONOMETRY

Tonometry is the process of exposing a liquid to a gas phase in such a way that each gas in the gaseous phase partitions to an equilibrium between the liquid and gas. This equilibration, in effect, imparts the PCO_2 and PO_2 of the equilibrating gas to the blood to which it is exposed within the tonometer. Equilibration by tonometry uses gases of known fractional composition, humidified at 37 °C to give a saturated water vapor pressure of 47 mm Hg. The PCO_2 or PO_2 of such gases is calculated according to Dalton's law (see section on behavior of gases). Tonometry is used to treat blood samples for various special studies that are requested only rarely in most hospital settings and for preparing quality control material in whole blood. Direct determination of P_{50} and of standard bicarbonate are two applications of tonometry.

Tonometry may be achieved by simple homemade assemblies or by commercially available equipment. Some commercially available tonometers use a thin-film technique. It consists of a glass or plastic cup fitted on a shaft and enclosed in a humidified chamber whose temperature is maintained at 37 °C. A few milliliters of blood is placed in the cup, and gas flow is initiated to continuously flush the inside surface of the cup with the humidified gas. A controller unit causes the cup to rotate rapidly and periodically in short bursts, so that the blood in the cup is thrown in a thin layer over the inside walls. Another form of tonometry is the bubble technique. It uses a syringe that is specially constructed to allow gas to be introduced and humidified through the plunger. During tonometry, the syringe is laid in a thermostatically controlled aluminum heat block. Additional detail on tonometry and its applications can be found in a previous edition of this textbook. Reference conditions for tonometry have been recommended by a committee of the International Federation of Clinical Chemistry and Laboratory Medicine (IFCC).[49]

DETERMINATION OF PCO_2, PO_2, AND pH

The instruments used for determination of PCO_2, PO_2, and pH are highly automated. Proper specimen collection and handling are critical for accurate determinations.

Specimens

Whole blood is the most likely specimen for a clinical laboratory to receive for gas analysis and may be obtained from any site accessible to vascular catheterization or entry. These sites commonly are the vessels of the extremities, but special studies may require access to the chambers of the heart and great vessels of the chest. Analysts should recognize that some specimens are difficult to obtain and should be handled with utmost care. Sometimes the volume of the specimen collected for analysis, particularly from premature neonates, has to be as small as possible without sacrificing specimen quality and analytical accuracy.

Differences in measured blood gas values between arterial and venous are most pronounced for PO_2. In fact, PO_2 is the only clinical reason for the more difficult arterial collections. PO_2 is generally 60 to 70 mm Hg lower in venous blood after O_2 is released in the capillaries, whereas PCO_2 is 2 to 8 mm Hg higher in venous blood. pH is generally only 0.02 to 0.05 pH units lower in a venous sample.

Quality assurance of blood analysis for gases and pH is dependent on control of preanalytical error (i.e., on proper collection and handling of the specimen) and on control of the analytical instrument and testing process. Because laboratory personnel do not always control collection of arterial

or venous specimens, they must work closely and cooperatively with physicians, nurses, respiratory therapists, and other personnel who obtain these samples. Guidelines for controlling preanalytical errors have been published by the NCCLS.[77]

Arterial puncture carries a slight medical risk and under no circumstances should it be undertaken by anyone who has not been properly trained to perform it. Arterial puncture is always done with a syringe and needle. No tourniquet is used, and no pull or very gentle pull is applied to the plunger of the syringe as the arterial blood pressure pushes blood into the syringe. An NCCLS-approved standard, H-11A3, describes appropriate procedures.

Venous blood for measuring blood gases and pH is best collected with a needle and syringe, although some laboratories also accept specimens drawn to a complete fill of an evacuated tube containing a dry heparin salt. In the collection of venous blood from an arm vein, the specimen should be obtained after release of a tourniquet, and the patient should not be allowed to flex the fingers or clench the fist. Prolonged application of a tourniquet and/or muscular activity will decrease venous PO_2 and pH. Placement of indwelling catheters with heparin locks for short- and long-term intravenous therapies is common and the catheter can serve as a port for the specimen collection if it is thoroughly flushed with blood (usually 5× the catheter volume) before the specimen is drawn. Failure to flush the lock properly has unpredictable effects on measured quantities and is frequently indicated by bizarre, nonphysiological results.

Arterial or venous specimens are best collected anaerobically with lyophilized heparin anticoagulant in sterile syringes with capacities of 1 to 5 mL. Although in theory glass syringes are preferred to prevent the exchange of gases through the syringe wall, most blood gas syringes today are plastic and the exchange of gas that occurs within 1 hour is trivial. Lyophilized heparin is preferable to liquid heparin because the liquid heparin, which has atmospheric PO_2 and PCO_2 values, dilutes the sample, with the effect being greatest when the syringe is not completely filled. If liquid heparin is used, the size of the syringe, the concentration and volume of liquid heparin, and the volume of blood drawn into the syringe are important. Adequate anticoagulation (~0.05 mg heparin/mL blood) can be achieved by drawing enough liquid heparin solution into the syringe in such a way as to wet the interior of the barrel over the maximum inner surface area of the syringe and ejecting air and excess heparin in such a way as to leave the dead space of the syringe filled with heparin. The syringe dead space is roughly 0.1 mL, and thus when a sterile heparin solution of 500 U/mL (5 mg/mL) is used, the dead space will hold 0.5 mg of heparin. In a 1-mL syringe, or if only 1 mL of blood is drawn into a 3- or 5-mL syringe, the blood will be diluted with up to 10% heparin solution. An increasing ratio of heparin to blood (Table 27-5) can have an increasingly marked effect on measured PCO_2 and the parameters calculated from it.[35] In one study, dilution with 10% heparin having an atmospheric PCO_2 of 0.25 mm Hg led to a 10- to 20-mm Hg decrease in blood PCO_2.[45] Before analysis, mixing of the sample by simple but vigorous rolling of the syringe between the palms is usually adequate to establish the desired homogeneity whether liquid or lyophilized heparin is used.

TABLE 27-5 Changes in pH, PCO_2, Base Excess, PO_2, and Actual Bicarbonate With Different Volumes of Heparin Solution in Venous Samples

	Percentage Volume of Heparin Solution in Blood			
	2	4	10	20
pH	7.37	7.37	7.37	7.36
PCO_2 (mm Hg)	51.0	48.8*	44.2*	39.0†
PO_2 (mm Hg)	32.2	35.2	36.8	38.2
Actual HCO_3 (mmol/L)	29	28‡	25	22†

From Hutchison AS, Ralston SH, Dryburgh FJ, et al. Too much heparin: Possible source of error in blood gas analysis. Br Med J 1983;287:1131-2. Significance of difference from percentage volume of 2: *$p < 0.01$; †$p < 0.001$; ‡$p < 0.05$.

Anaerobic technique for collection means no or minimal exposure of blood to atmospheric air. The PCO_2 of dry air is about 0.25 mm Hg, which is much less than that of blood (~40 mm Hg). Thus the CO_2 content and PCO_2 of blood exposed to air will decrease, and blood pH, which is a function of PCO_2, will rise. The PO_2 of atmospheric air (~155 mm Hg) is approximately 60 mm Hg higher than that of arterial blood and approximately 120 mm Hg higher than that of venous blood. Therefore blood from patients breathing room air that is exposed to atmospheric air gains O_2. In contrast, blood with PO_2 exceeding 150 mm Hg, as will occur in patients undergoing O_2 therapy, loses O_2 on exposure to air. Even with care in sample handling, blood can be exposed to air simply from the air in the needle and the syringe hub dead space. Error will be minimal if the resulting bubble is ejected immediately upon removing the needle from the puncture site. The potential effect of small bubbles on blood gas results was clearly demonstrated in one study in which a 100-μL bubble of room air was added to 10, 2-mL blood samples with PO_2 values between 25 and 40 mm Hg. In these samples, PO_2 increased an average of 4 mm Hg in only 2 minutes, whereas PCO_2 decreased 4 mm Hg.[74] Numerous small air bubbles have similar effects. Thus when a full syringe is disconnected from a needle or cannula, it should be held tip up, a drop of blood ejected from it, and a tightly fitting cap placed on the tip of the hub.

Arterialized capillary blood is sometimes an acceptable alternative to arterial blood when blood losses need to be minimized, when an arterial cannula is not available, or to prevent repeated arterial puncture. Freely flowing cutaneous blood originates in the arterioles and corresponds closely to arterial blood in composition. However, arterialized capil-

lary blood is not acceptable when systolic blood pressure is less than 95 mm Hg, in cases of vasoconstriction, from patients on O_2 therapy, from newborns during the first few hours after birth, or in newborns with respiratory distress syndrome. These situations pose a particular risk of admixture with blood from the venules, resulting in erroneously low PO_2 values. Capillary puncture should be preceded by warming the selected skin puncture site for 10 minutes to achieve vasodilation and adequate blood flow through local capillaries. For collection from the finger of a child or adult or from an infant's heel, warming may be accomplished by immersing the arm or leg in water warmed to 45 °C. The first blood drop to appear should be wiped away, and subsequent free-forming drops taken up in a capillary collection tube containing lyophilized heparin. Only free-flowing blood provides a satisfactory sample, and taking up the drops as soon as they form minimizes aerobic exposure. Appropriate capillary tubes hold 70 to 300 µL of blood, and the larger-diameter tubes require mixing. A flea (a slender wire approximately 5 mm in length) is immediately inserted after filling, and a magnet is used to move the flea back and forth.

Transport and analysis of specimens should be prompt. Physicians who use blood gas and pH measurements in acute care management usually require very rapid turnaround times between specimen acquisition and reporting of results. Ideally, specimens should never be stored before analysis. However, delayed analysis of up to 1 hour will have a minimal effect on reported values from most samples. The pH of freshly drawn blood decreases on standing at a rate of 0.04 to 0.08 pH unit/hr at 37 °C, 0.02 to 0.03/hr at 22 °C, and <0.01/hr at 4 °C. The decrease in pH is accompanied by a corresponding decrease in glucose and an equivalent increase in lactate. PCO_2 increases by ~5 mm Hg/hr at 37 °C, 1 mm Hg/hr at 22 °C, and only ~0.5 mm Hg/hr at 2 °C to 4 °C. The primary cause of these changes is glycolysis by leukocytes, platelets, and reticulocytes. In freshly drawn blood with a normal PO_2 that is maintained anaerobically, cell respiration causes PO_2 to decrease at a rate of ~2 mm Hg/hr at room temperature but 5 to 10 mm Hg/hr at 37 °C. Adverse effects of glycolysis and respiration on pH, $ctCO_2$, PO_2, and PCO_2 of blood can best be prevented by analysis within 30 minutes after collection. If analysis must be delayed or if circumstances create a risk of delay, the syringe or tube containing the blood should be immersed in a mixture of ice and water until analysis is possible. Under these conditions, changes are negligible because glycolysis is inhibited. However, if plastic syringes are stored in ice water there is a risk of significant increases in PO_2, when the actual blood PO_2 is low, because of diffusion of the gas through the plastic. With state-of-the-art blood gas instrumentation, introduction of a chilled sample carries little risk of low-temperature effect on measurements because the thermal equilibration of the sample to 37 °C is rapid and complete.

The aforementioned small changes in values that can be expected with delays in analysis are true *only* when the white blood cell count (WBC) is normal or only slightly elevated. Glycolysis and the resulting effects on pH, PO_2, and PCO_2 increase dramatically with markedly elevated WBC, such as occurs in leukemia. Experiments have shown that PO_2 decreases 20 mm Hg in just 2 minutes and 40 mm Hg in only 5 minutes with WBC values greater than 100,000/µL.[20,46] Indeed, with these types of WBC values, it is virtually impossible to overcome this effect. Even after immersing the sample in ice, thermal equilibrium takes at least 3 to 5 minutes, allowing significant PO_2 loss before the contents reach 2 °C. The only alternative to obtain accurate blood gas values on such patients is immediate on-site analysis by use of a point-of-care device or by taking the blood gas analyzer to the patient.

Instrumentation

Reference methods for blood gas and electrolyte determinations have been described in detail by the IFCC.[67] A schematic diagram characteristic of a typical instrument is shown in Figure 27-4. Electrochemical principles and structural features of electrodes are discussed in Chapter 4. Prominent manufacturers of blood gas equipment include Roche Scientific Corp., Bayer Diagnostics, Instrumentation Laboratory, Nova Biomedical, and Radiometer America, Inc. Readers are referred to these manufacturers for details and operational features of specific instruments.

Recent developments in instrumentation have included "stat. profile" equipment for point-of-care or bedside

testing.[36,112] Almost all manufacturers now produce small, portable, stand-alone, easy-to-operate instruments designed for "satellite lab" operations, and some hand-held devices that use disposable electrodes, such as the I-STAT instrument, are also available.[36] Such instruments often combine measurement systems for blood gases and pH with ISEs for electrolytes, glucose, urea nitrogen, and hematocrit or hemoglobin. Although design and construction may differ significantly from those used in laboratory instrumentation, the principles of analysis, especially for blood pH and gases, are not novel. Readers are referred to the manufacturers' literature and to Chapter 12 for a discussion of POCT.

The operation of a traditional blood gas instrument begins with the operator presenting a blood specimen at the sample probe. A keyboard-entered command to sample a specimen initiates uptake of the sample through the probe by a peristaltic pump that loads the chamber with 60 to 150 µL of the fluid sample. The pump is under microprocessor control to pause after admission of the sample to let the sample reside in the chamber long enough to allow thermal equilibration and for the measurements to be completed. On completion of measurement, the pump pushes the sample to waste, while output is being made available on a display, a printed tape, and often to a laboratory information system through an interface.

The instrument (see Figure 27-4) is designed so that a manually or microprocessor actuated valve (V) admits calibrator gases, standard buffers, or a sample to a small chamber (C) maintained by a fluid or metal bath (B) to a constant temperature of 37 °C ± 0.1 °C. Measuring and reference electrodes (E) protrude into this chamber. In the pH calibration phase of the instrument, high pH standard buffer and low pH standard buffer are alternately admitted into the chamber and electronic responses of the upper and lower limits of a linear pH curve are established. In the gas calibration phase, gas mixtures with high and low fractional concentrations of O_2 and CO_2 are alternately admitted into the chamber and electronic responses of the upper and lower limits of linear PO_2 and PCO_2 curves are set. In the measurement phase, an anaerobically collected blood sample is admitted.

Most instruments are designed to be self-calibrating. Under the command of the microprocessor, calibrator gases and buffers are cycled at short intervals through the chamber, and electronic responses are continually monitored and reset to the constants initially entered for high and low PCO_2 and PO_2 and high and low pH of the calibrator materials. In the United States, the regulations written for the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88) mandate one point calibration every 30 minutes or within 30 minutes of every patient's sample and two point calibrations every 8 hours.

Electrodes

The tip of the pH measuring electrode is made of H^+-sensitive glass (see Chapter 4), and aside from specialized construction and miniaturization for application in the blood gas chamber, most pH measuring and reference electrodes differ little from those of free-standing pH meters.

Construction of PCO_2 and PO_2 electrodes is shown in Figures 4-4 and 4-8. The gas electrodes are fitted at the tip with gas-permeable membranes held in place with O-rings. Inside these membranes are electrolyte solutions in contact with the measuring and reference elements of the electrode. The membrane of the PCO_2 electrode usually consists of Teflon or silicone rubber approximately 25 µm thick. The electrolyte solution is a thin film containing sodium bicarbonate at 0.005 mol/L and sodium chloride (NaCl) at 0.1 mol/L saturated with AgCl. A spacer of nylon net or cellophane lies between the solution and the H^+-sensitive glass of the measuring element proper. As CO_2 diffuses from the sample into the electrolyte solution, the slight rise in $[H^+]$ from its hydration reaction is measured as ΔpH by an especially sensitive potentiometer and is transformed to Δlog PCO_2 electronically.

The membrane of a PO_2 electrode in a standard blood gas analyzer is usually ~20-µm thick polypropylene. The electrolyte solution is a thin film of phosphate buffer saturated with AgCl but also containing KCl, and is in contact with the polarized platinum cathode and the Ag/AgCl anode. As O_2 diffuses into the electrolyte, it reacts with the cathode to cause current to flow; the generated current is measured. The sensitivity ($\Delta I/\Delta PO_2$, change in current per millimeter of mercury) of a PO_2 electrode with a polypropylene membrane is around 20 pA/mm Hg. Most point-of-care analyzers use disposable electrodes, eliminating the necessity to change membranes.

Optical Approaches to Blood Gas Measurement

Optical approaches to measuring pH and blood gas parameters have recently been used in some newer point-of-care devices. These devices use single-use, dry chemistry cartridges to determine pH, PO_2, PCO_2, and in some cases electrolytes. The OPTI Critical Care Analyzer device from Osmetech, Inc. uses a series of fluorescent sensor molecules that are specific for the different gases, electrolytes, or glucose. The NPT7 from Radiometer is another point-of-care device that uses optical technologies for pH and blood gas measurement.[12] PCO_2 is determined by infrared absorbance at three wavelengths, 4228, 4268 and 4308 nm, with 4268 nm being the peak absorbance for CO_2 in plasma. The PO_2 sensor in this device uses a phosphorescent dye dissolved in a polyvinyl chloride (PVC) membrane. The dye is a Pd complex of a porphyrin molecule, and the instrument detects quenching of the phosphorescence by O_2 (see Figure 27-5). Finally the NPT7 measures pH with a pH-sensitive dye and performs co-oximetry with a 128 wavelength spectrophotometer.[12] It is likely that these types of single-use, dry chemistry approaches will become more popular in POCT. The challenges inherent to this or other types of POCT are discussed in Chapter 12.

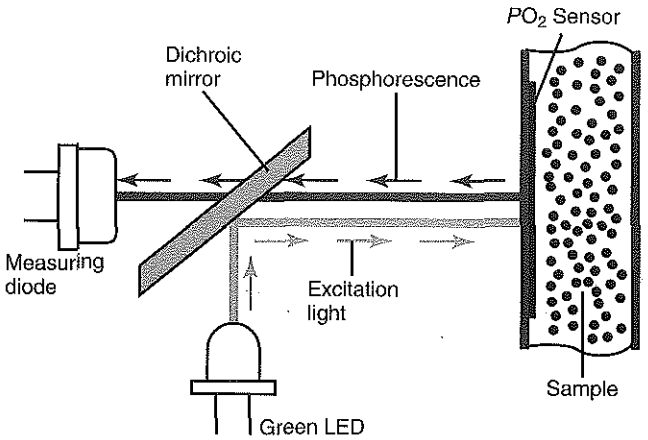

Figure 27-5 The optical system for measurement of PO_2. The optical system for PO_2 is based on the ability of O_2 to reduce the intensity and lifetime of phosphorescence from a phosphorescent dye that is in contact with the sample. The optical system comprises a green (519-nm peak) light-emitting diode (LED, that emits light, which is reflected by a dichroic mirror onto the PO_2 sensor. Because of the phosphorescence, red light (672-nm peak) is emitted back through the dichroic mirror and onto a photodetector. *(From Boalth N, Wandrup J, Larsson L, et al. Blood gases and oximetry: calibration-free new dry chemistry and optical technology for near-patient testing. Clin Chim Acta 2001;307:225-33.)*

Significant Figures of Results

Contemporary instruments commonly display pH readings to three decimal places and PCO_2 and PO_2 readings to one decimal place. The pH should be reported to two decimal places, and PCO_2 and PO_2 as integers (when the unit is mm Hg).

Calibration

Because electrodes are not stable over long periods of time, frequent calibration of pH, PCO_2, and PO_2 is required.

The pH measurement system is calibrated against primary standard buffers admitted either manually or automatically into the sample chamber. The buffers are phosphate solutions that should meet National Institutes of Standards and Technology (NIST) specifications. Calibration buffers meeting NIST specifications are available from the manufacturer of an instrument, usually in containers of appropriate size and shape for mounting as a reservoir on the instrument. The pH values of the low and high calibrator buffers are set by the manufacturer but always lie close to 6.8 and 7.4 at 37 °C. The tolerance of the specified values should be less than or equal to an SD of ±0.003 to achieve SDs of ±0.005 to ±0.01 in measuring blood pH. Unopened containers should be stored at room temperature. When visual observation or an instrument display warns of low concentrations in the reservoir, recommended practice is to replace the reservoir with a newly opened container rather than to replenish fluid in the current one. Pooling several almost empty containers is not recommended.

PCO_2 and PO_2

Calibration of the gas measurement systems is made against gases of known O_2 and CO_2 composition, admitted into the sample chamber. Compressed gases, with a certificate of analysis provided by the manufacturer, are most used as primary standards. Pure O_2, CO_2, and N_2 may be obtained in individual tanks and mixed as desired with a precision gas mixer in the blood gas laboratory, but this is seldom done today. The "low gas" mixture for calibration usually has a fractional composition of 5% CO_2, 0% O_2, and 95% N_2. The "high gas" mixture has a fractional composition of 10% CO_2, 20% O_2, and 70% N_2. These compositions correspond roughly to a calibration range of 38 to 76 mm Hg for PCO_2 and 0 to 152 mm Hg for PO_2.

The mode of calibration is determined by the design of the instrument. Most instruments contain a barometer or a transducer responsive to P(Amb) so that barometric pressure is always known to the microprocessor. With such instruments, only a keyboard entry of the fractional composition of O_2 and CO_2 in low and high calibrator gas mixtures needs to be made. Today, most analyzers autocalibrate without the necessity for user input. The microprocessor will calculate the values for PO_2 and PCO_2 (according to Dalton's law) for gases saturated with water vapor at 37 °C.

Liquid-Gas Difference of a PO_2 Electrode

When calibration gases are used to standardize a system, a particular property of the PO_2 electrode needs to be considered. This property is called the *liquid-gas* or *blood-gas difference.*

PO_2 and PCO_2 electrodes are alike in that gas diffusing from a liquid or gaseous sample passes through a gas-permeable membrane into an enclosed electrolyte solution that is in contact with measuring and reference elements. In both electrodes, the rate of diffusion of a gas through the membranes is slower from a liquid phase than from a gaseous phase. However, PCO_2 and PO_2 electrodes use different principles of measurement. Because CO_2 is not consumed by the PCO_2 electrode, the rate of its diffusion through the membrane is not limiting, and equilibrium is achieved between the PCO_2 of the sample and the inner bicarbonate solution. Thus the PCO_2 electrode senses PCO_2 to the same extent whether the sample is liquid and diffusion is slow or the sample is gaseous with faster diffusion.

By contrast, O_2 passing the membrane of a PO_2 electrode enters an irreversible reaction at a polarized cathode so that current generated by the reaction is proportional to the amount of O_2 reduced. The amount of O_2 available for consumption depends on the rate of diffusion of O_2 through the membrane. A steady state is achieved when the rate of diffusion equals the rate of reduction. Thus the electrode responds to a greater degree to O_2 diffusing from a gaseous phase than from a liquid phase.

The liquid-gas difference for a PO_2 electrode becomes significant when an electrode is calibrated with gas but used to

measure PO_2 in blood. The difference is usually expressed as a ratio of PO_2 (gas sample) to PO_2 (liquid sample). For most electrodes, the ratio is commonly 1.02 to 1.06. For routine clinical work, a ratio of 1.04 is frequently assumed rather than determined. For the highest accuracy of blood PO_2 analysis, the ratio for a particular electrode can be determined with tonometered blood versus the same gaseous mixture and applied as a correction factor to measured PO_2.

Quality Assurance

The elements of good quality assurance of blood gas and pH measurements include proper maintenance of the instrument, use of control materials, verifying electrode linearity, checking barometer accuracy, and accurately measuring temperature.

Maintenance of Instrumentation

Sophistication of contemporary equipment and availability of high-quality calibrator materials have made reliable and accurate determination of blood pH and gases primarily a matter of meticulous maintenance and control of the equipment and proper collection and handling of specimens. Software programs of the instrument's microprocessor often provide display warnings and diagnostic routines that alert the operator and assist in the trouble-shooting process. Nevertheless, regular maintenance and close adherence to the manufacturer's recommended procedures are essential for satisfactory operation. The frequency with which maintenance should be scheduled is in direct proportion to the volume of analyses performed in the laboratory. The manufacturer's suggested schedule should be considered a minimum guideline, with experience relied on to indicate maintenance frequency.

Cleanliness of the sample chamber and path is especially important. Automatic flushing to cleanse the sample chamber and path after each blood sample measurement is a feature of most instruments without disposable electrodes. When it is not, then manual modes of flushing recommended by the manufacturer should be faithfully practiced. Despite proper flushing, however, complete or partial clogging of the chamber or path or both may occur. Frequency of clogging is often related to the number of heparinized capillary blood samples that are analyzed. Fibrin threads and small clots may be present in the specimen or may form while the sample resides in the warm chamber. If allowed to remain, they can affect subsequent measurements or calibrations by interfering with the contact of blood, buffers, or gases with electrode membranes. Visibility of the path through the heat sink is helpful for detecting clogs, dirt, and bubbles. Bubbles that fail to rinse out can be a particular problem if they settle on an electrode.

Prompt and reliable service by the manufacturer or an in-house biomedical engineer is essential for a laboratory performing many analyses per day. Also important is ready availability of goods from the manufacturer or from laboratory supply houses, such as calibrator materials (pH buffers and gases of certified quality), replacement membranes, and small parts for the maintenance of electrodes.

Proficiency testing mandated by federal law in the United States (CLIA '88) has assumed new importance for quality control of blood gas analysis. These rules became effective in January, 1991, and set criteria for satisfactory interlaboratory performance as follows: pH, target value ±0.04; PO_2, target value ±3 SD; and PCO_2, target value ±8% or ±5 mm Hg, whichever is greater. The risks of failure in a testing event are greatest for PCO_2, according to a computer model.[34] The significance of proficiency testing and the penalties for failure place a new incentive on faithful performance of internal control measures and effective response to failures of quality control. At the same time, pressures to control costs have raised the question of how often and how many concentrations of control materials are necessary to monitor intralaboratory performance effectively. The facile answer is as often and as many concentrations as it takes to maintain confidence in the measurement systems. The regulatory answer per CLIA '88 is one concentration of control every 8 hours, with the entire range of control concentrations covered in every 24-hour period. The CAP requires at least two concentrations of controls every 8 hours. In many laboratories, however, the practical answer is to run on every instrument in use, at least once per shift, three concentrations of control for pH, PO_2, and PCO_2, and always on completion of maintenance and troubleshooting procedures.

Newer analyzers, particularly the smaller satellite lab and point-of-care instruments, frequently have an "auto quality control (QC)" feature or use "electronic QCs."[109] Auto QC consists of on board QC material that is automatically analyzed by the instrument at designated intervals that fulfill regulatory requirements. Electronic QC is most common in devices with disposable electrode cartridges and consists of cartridges that verify the electronic specification of the instruments. To be acceptable to most regulatory agencies these electronic QC systems must provide a quantitative result rather than just a qualitative "ok" or "not ok."[109] Although both of these features are very user friendly, ensure proper instrument performance, and are approved by regulatory agencies, there is debate as to how well they can ensure the quality of the entire analytical performance. Such approaches do not assess operator performance or sample handling conditions that can affect blood gas results. The NCCLS has recently published a guideline for electronic QC and other alternative QC approaches for devices that use disposable electrodes.[76] For further discussion of these issues see Chapter 12 on POCT.

Control Materials

Traditionally, QC materials can be commercial blood-based fluids or aqueous fluids. Alternatively, independent standard buffers can be used for pH control and tonometered whole blood for PCO_2 and PO_2 control.

Blood-Based and Fluorocarbon-Based Control Materials. Commercial blood-based control material usually

consists of tanned human erythrocytes suspended in buffered medium and sealed in vials with a gas mixture of known O_2 and CO_2 content. Nonblood fluorocarbon materials with O_2-carrying properties similar to those of blood are also available. These products usually are made at three concentrations of pH, PCO_2, and PO_2. Unopened, these types of control material have the advantages of a long shelf life in the refrigerator; 20 to 28 days for the tanned erythrocytes and even longer for the others. The buffered medium allows for control of pH along with that of PO_2 and PCO_2. Within-day and day-to-day consistency in the lifetime of a given lot have been reported to be excellent; within-day coefficients of variation over the range of concentrations were 1% to 2% for pH, PCO_2, and PO_2.

Aqueous Fluid Control Materials. These materials consist of a buffered medium sealed in vials with gas mixtures; the fluid is equilibrated with the gas by vigorous shaking by hand for a prescribed length of time immediately before the vial is opened, and a sample is admitted to the instrument. Coefficients of variation of 0.1% for pH, 2.5% for PCO_2, and 3.2% for PO_2 are common for these types of materials. The disadvantages of aqueous controls stem from their dissimilarity to blood. Lower viscosity and surface tension confer different washout characteristics and impair their ability to reflect clogging. Greater electrical conductivity reduces their effectiveness to detect inadequate grounding, and lower thermal coefficients make them slower to detect failures of temperature control. These disadvantages are most apparent with respect to PO_2, where a fluorocarbon-based matrix is superior. Nevertheless, aqueous commercial controls are far and away the most commonly used. In some laboratories, tonometered controls are used as adjuncts to commercial controls, but this is becoming rare because of the reliability and ease of use of modern blood gas analyzers.

Tonometered Whole Blood. Quality control of PO_2 and PCO_2 by tonometered blood is considered the method of choice because the control material most nearly approximates patients' samples in its interaction with gas electrodes. Tonometered blood is acknowledged to have greater sensitivity for detecting deterioration of the gas-permeable membranes of electrodes than do aqueous fluid controls. The substantial disadvantages are the time required for tonometry, particularly if two or three concentrations of control are desired; difficulties in frequently obtaining fresh, normal blood samples; the necessity for repeated calculation (and risk of miscalculation) of PCO_2 and PO_2 of the equilibrating gases; the necessity to keep special gas mixtures; and its inapplicability to control pH measurement. To prepare tonometered (gas-equilibrated) samples for use as controls, NCCLS Document C46-A recommends a fresh, single-source blood specimen.[77] Because of the difficulties in obtaining and measuring tonometric samples, the NCCLS recommends for laboratories where tonometry is not directly available that there be an arrangement with nearby laboratories or the manufacturer to make tonometric samples available when necessary.[77]

Quality Control Data. Data obtained from assays of blood gas and pH control materials may be handled in the same way as data from other clinical chemistry determinations (i.e., mean, SD, and coefficient of variation, and control and confidence limits for construction of Levey-Jennings plots). As stability of commercial aqueous control materials is generally several months, vendors often provide data reduction programs that standardize and simplify documentation. However, the resulting reports are temporally delayed and are most useful for meeting accreditation requirements as opposed to real-time corrective or preventive action. They are however useful to compare long-term performances with other laboratories. Equally important features of quality assurance to an active blood gas service are the "sixth sense" of practiced operators for detecting subtle manifestations of deterioration of instrument performance and the suspicion of trouble expressed by clinicians.

Barometer

A barometer, whether built into the instrument or free standing, should periodically be checked for accuracy. Because the classic mercury-filled barometer has become a rarity in clinical laboratories, the most reliable reference is local P(Amb) as recorded by the nearest official meteorological station, obtained by a phone call or via the Internet, and corrected for any altitude difference.

Temperature Control

Because an exact temperature of 37 °C is essential for the accurate measurement of blood gases and pH, state-of-the-art instrumentation is furnished with thermal sensors embedded in the heat sink around the measuring chamber and communicating to the microprocessor. Audible or visible alarms signal deviation of temperature outside of preset tolerances (usually 37 °C ± 0.1 °C). Also of value is to use temperature-sensitive buffers, such as HEPES or TES, in pH quality assurance procedures.

Sources of Analytical Error

General causes of analytical error are calibration of the instrument with incorrect set points for pH buffers or calibrator gases, degraded calibration materials, failure of temperature control of the measurement chamber, or a dirty sample chamber or path. Incorrect calibration may arise from wrong entries made for buffer or gas values into the microprocessor, from incorrect manual calculations of PCO_2 and PO_2 values by Dalton's law for calibrator gases, or from using gases that are dry because the humidification device is not working properly.

A source of error for the PO_2 electrode is using it in a range above 500 mm Hg when it has not been calibrated for use in this range. Measurements of PO_2 are particularly sensitive to temperature error. To keep systematic error to 1%

to 2%, the temperature control at 37 °C must be within ±0.1 °C. The PO_2 electrode liquid gas difference can introduce a 2% to 6% error. This error will be less when a liquid-gas correction factor is incorporated into the algorithm that generates results. Gases other than O_2 present in a blood sample may affect performance of the PO_2 electrode. The anesthetic gases halothane and nitrous oxide have a direct effect because both can be reduced at the polarized cathode in competition with O_2. Under most circumstances, however, these effects are small and can be ignored.

TABLE 27-6 Temperature Correction Formulas Recommended by the NCCLS[77]

pH	$pH = pH_m + [-0.0147 + 0.0065(7.4 - pH_m)](t - 37)$
PCO_2	$PCO_2 = PCO_{2,m}10^{0.019(t-37)}$
PO_2	$PO_2 = PO_{2,m}10^{\left[\frac{(5.49\times10^{-11}PO_2^{3.88})+0.071}{(9.72\times10^{-9}PO_2^{3.88})+2.30}\right](t-37)}$

Reference Intervals[101]

Reference intervals for arterial blood PO_2, SO_2, PCO_2, and pH are extensively described in Chapter 56. Arterial blood PO_2, low at birth, rises to an adult concentration of 83 to 108 mm Hg. An empirical relationship of age to PO_2 is given by the following equation:

$$PO_2, \text{mm Hg} \simeq (-0.27 \times \text{age [y]}) + 104$$

The cause of the fall in PO_2 with age is a gradual increase in pulmonary venoarterial shunting. Values for PO_2 and PCO_2 will decrease with increasing altitude but compensatory mechanisms keep pH values the same. Saturation fraction, SO_2(aB), may be as low as 0.40 at birth but thereafter is 0.95 to 0.98. The FO_2 is 0.90 to 0.95 in healthy adults. The P_{50} corrected to pH 7.40 is 18 to 24 mm Hg for newborns and 24 to 29 mm Hg for adults.

Arterial blood PCO_2 ranges at sea level are somewhat lower for infants than for adults. The range for adults is 35 to 45 mm Hg. Values decrease with altitude above sea level at a rate of 3 mm Hg/km (5 mm Hg/mile). A physiological change occurs with change in posture; PCO_2 is 2 to 4 mm Hg higher for a sitting or standing person than for one in the supine position. During pregnancy, PCO_2 falls gradually to a mean of about 28 mm Hg just before term.

Arterial blood pH, in the first few hours of life, may vary over a range of 7.09 to 7.50, but thereafter is 7.35 to 7.45. The pH of arterial plasma, separated anaerobically at 37 °C, is 0.01 to 0.03 units greater than that of a corresponding whole blood sample, but the difference is not physiological. It arises instead from the effect of erythrocytes on the junction potential of the pH electrodes.

Temperature Correction of Measured pH, PCO_2, and PO_2

In the Henderson-Hasselbalch equation, pK' and α are used as constants for a temperature of 37 °C. The temperature-controlled sample chamber of an instrument is specified to be 37 °C ± 0.1 °C, and it is at that temperature that all measurements of pH and partial pressure of gases are made. The body temperature of a febrile patient may be elevated to 40 °C to 41 °C, or a patient may be made hypothermic for cardiopulmonary bypass surgery and have a temperature as low as 23 °C. Most blood gas instruments, on keyboard entry of a patient's actual temperature, can calculate and present temperature-corrected pH and PCO_2 and calculated values derived from the temperature-corrected primary data. Algorithms used by some manufacturers in their instruments have been listed,[6] and these are very similar or identical to the algorithms shown in Table 27-6 and specified by the NCCLS.[77]

Correction of pH and PCO_2 to the actual temperature of the patient is usually omitted in states of hyperthermia. The magnitude of correction for 40 °C (104 °F) would be +0.045 for pH, and +13% for PCO_2. Therefore correction of PCO_2 can be important if the value is to be used in pulmonary gas exchange studies such as shunt calculations, but unnecessary for the clinical management of assisted ventilation. However, significant disagreement exists with respect to hypothermic states. There are two basic strategies used by anesthetists for managing hypothermia patients. In the pH-stat. method, the measured pH is corrected to the actual body temperature of the patient and then maintained as close to 7.4 as possible by introducing 3% to 5% CO_2 in the inhaled ventilator gas. Alternatively, in the α-stat. strategy, uncorrected values are used to keep the pH and PCO_2 close to the 37 °C reference value.[97] In most situations, the α-stat. method is used, primarily since it is technically easier to perform and may be slightly safer.[97] However, in children undergoing deep hypothermia and circulatory arrest, the pH-stat. strategy has been shown to be more effective at protecting the brain, and is the recommended strategy.[52]

The equation shown in Table 27-6 illustrates the complexity of the calculation to correct PO_2 to the patient's body temperature. Complexity is unavoidable because at PO_2 less than 100 mm Hg ($SO_2 \leq 0.95$), the hemoglobin-O_2 dissociation curve is shifted to the left by the decrease in temperature and by the concomitant rise in pH (see Figure 27-3). For temperature corrections of PO_2 between 100 and 400 mm Hg, accurate formulas become even more complicated.[2] The most accurate calculation of the temperature variation of PO_2 is made by iterative calculations when the only necessary parameters are the temperature coefficients of the P_{50} and the solubility coefficient of O_2 (αO_2). Several analyzers perform such calculations.

As an example of the impact of body temperature on PO_2 values, the following is given as an example. If at 37 °C and an SO_2 of 95% a patient's PO_2 is 75 mm Hg, the PO_2 would

be 28 mm Hg at 22 °C. Despite the dramatic and seemingly clinically significant difference, the total oxygen content of the blood obviously does not change with temperature. Furthermore, Severinghaus has shown that SO_2 changes by less than 2% between 0 °C and 42 °C[94] depending on the initial SO_2. Thus it has been recommended that PO_2 be reported at 37 °C and not temperature corrected except when the values are to be used in pulmonary gas exchange studies.[6] Others prefer to refer all values, along with temperature-specific reference intervals, to the patient temperature.

Taken together, prudent policy for the laboratory might be to generate and report temperature-corrected results for pH and PCO_2 only on the specific request of the physician. Furthermore, as per NCCLS recommendation, temperature-corrected results should never be reported without the original results measured at 37 °C.[77]

Continuous and Noninvasive Monitoring of Blood Gases

Obtaining arterial, venous, or capillary blood is an invasive procedure, and test results reflect conditions pertaining only to a single point in time. Repetitive sampling in intensive or acute care management carries risks, including infection and vascular complications. In premature infants particularly, repeated sampling imposes an undesirable blood loss. Decisive action during intensive cardiopulmonary care or cardiac surgery often demands either continuous monitoring or discrete real-time data for blood gases.

Extensive discussion of noninvasive and continuous modes of monitoring is beyond the purview of this text. However, laboratorians must be aware of them, because blood samples and standard analytical equipment remain the reference for monitoring the effectiveness of such devices, and because responsibility for quality assessment and review for them is often assigned to the clinical laboratory. Indeed, some regulatory agencies, such as the CAP, have developed guidelines for laboratory oversight of "alternative test systems" that include transcutaneous and in vivo monitoring devices. Such guidelines state that "in some cases traditional approaches to management, quality control, etc. may not be directly applicable but that systems must be in place to ensure that accurate results are generated."[21]

Pulse oximeters that continuously monitor SO_2Hb are common and generally reliable.[70] Older pulse oximeters were susceptible to error depending on placement and motion but newer technology has made these devices very reliable.[13,33] Transcutaneous monitoring of PCO_2 and PO_2 is a noninvasive continuous monitoring approach that has been around for more than 30 years and has had particular value and general success in neonatal and pediatric care.[11,54,71] These devices consist of gel-encased self-adhesive electrodes that heat the skin to 43 °C to 44 °C to arterialize the capillaries and facilitate diffusion of O_2 through the skin.[98] Although the electrodes differ considerably in appearance from those used on blood gas instrumentation, they operate on exactly the same electrochemical principle.

Transcutaneous monitoring of PO_2 can vary widely depending on whether the site of application reflects arterial, capillary, or venous blood flow. However, because there is little difference between arterial and venous PCO_2, transcutaneous monitoring of PCO_2 is less problematic and pulse oximeters can often serve as a surrogate for PO_2. Transcutaneous monitoring works best in areas of thin skin thus its popularity in neonates, and in settings of normovolemia. Decreased tissue perfusion and hypovolemia can make these devices unreliable. Nevertheless, their correlations with arterial blood gases are reasonable (r values ranging from 0.7 to 0.8) and they have been recommended for trending and monitoring. However, it is recommended that baseline arterial values be obtained before commencing noninvasive monitoring. Transcutaneous monitoring can also be used to monitor local tissue perfusion after certain surgical procedures and trauma.[86,98]

Transcutaneous PCO_2 values can be up to 80% higher than corresponding capillary or arterial blood values[54] of which 40% to 50% of the difference can be explained by the difference in the temperatures of measurement (44 °C versus 37 °C). Guidelines for transcutaneous measurement of PO_2 and PCO_2 have been published by a committee of the IFCC.[50]

In addition to monitoring PO_2 and PCO_2, new inline devices that also monitor pH, electrolytes, and hematocrit have recently been introduced to the market.[10] The VIA LVM Monitor (Metracor Technologies) is one of these and consists of a single-use inline cartridge consisting of six conventional electrodes. The cartridge is attached to an arterial line and upon operator command withdraws ~1.5 mL of blood into the cartridge where analysis takes place. The analytical time is about 60 seconds after which the blood is returned via the arterial line. Cartridges undergo a two-point calibration before being placed in service and a single-point calibration is used to flush the sensors after each analysis. Analysis can be repeated every five minutes and it is claimed that cartridges can be used for up to 72 hours. In a multicenter study results from 1414 paired sample measurements showed good agreement and correlation for results from an inline monitor compared with traditional laboratory methods.[10] A similar continuous inline analyzer that uses fiber optic technology is the Paratrend 7 from Agilent Technologies. The future of such devices will likely depend on cost versus benefits to patient care and outcomes.

CHAPTER 28

Hormones*

Michael Kleerekoper, M.D., F.A.C.E., F.A.C.B.

A hormone is a chemical substance produced in the body by an organ, cells of an organ, or scattered cells, having a specific regulatory effect on the activity of an organ or organs.[15] They are produced at one site in the body and exert their action(s) at distant sites through what is called the *endocrine* system. It is increasingly recognized that many hormones exert actions locally through what is termed the *paracrine* system. Finally, some hormones exert their action on the cells of origin, regulating their own synthesis and secretion via an *autocrine* system. The classic endocrine hormones include insulin, thyroxine, and cortisol. Neurotransmitters and neurohormones are examples of the paracrine system, and certain growth factors that stimulate synthesis and secretion of true hormones from the same cell are examples of an autocrine system.

Table 28-1 lists hormones that are commonly measured in clinical practice plus a few others to illustrate concepts. Biochemical, clinical, and analytical information for specific hormones and cytokines may be found in Chapters 22, 25, and 48 to 54.

CLASSIFICATION

Hormones are classified as (1) polypeptides or proteins, (2) steroids, or (3) derivatives of amino acids.

Polypeptide or Protein Hormones

Adrenocorticotropic hormone (ACTH), insulin, and parathyroid hormone (PTH) are examples of polypeptide or protein hormones. They are generally water soluble and circulate freely in plasma as the whole molecule or as active or inactive fragments. The half-life of these hormones in plasma is quite short (10 to 30 minutes or less), and wide fluctuations in their concentration may be seen in several physiological and pathological circumstances. These hormones initiate their response by binding to cell membrane receptors (on or in the membrane) and exciting a "second messenger" system, which continues the specific actions of these hormones.

Steroid Hormones

Steroid hormones (e.g., cortisol and estrogen) are hydrophobic and insoluble in water. These hormones circulate in plasma, reversibly bound to transport proteins (e.g., cortisol-binding globulin and sex-hormone binding globulin) with only a small fraction free or unbound available to exert physiological action.[5,8,17] The half-life of steroid hormones is 30 to 90 minutes. Free steroid hormones, being hydrophobic, enter the cell by passive diffusion and bind with intracellular receptors either in the cytoplasm or the nucleus.[3]

Amino Acid–Related Hormones

Thyroxine and catecholamine are examples of hormones that are derived from amino acids; they are water soluble and circulate in plasma either bound to proteins (thyroxine) or free (catecholamines). Thyroxine binds avidly to three binding proteins and has a half-life of about 7 to 10 days, and the free and unbound catecholamines such as epinephrine have a very short half-life of a minute or less. As do the water-soluble peptide and protein hormones, these hormones interact with membrane-associated receptors and use a second messenger system.

RELEASE AND ACTION OF HORMONES

The physiological functions of hormones have been broadly categorized into those that (1) affect growth and development, (2) exert homeostatic control of metabolic pathways, and (3) regulate the production, use, and storage of energy. The descriptions below illustrate examples of these functions and mechanisms of control of hormone secretion.

*The author gratefully acknowledges the original contribution by Dr. Ronald J. Whitley on which portions of this chapter are based.

TABLE 28-1 Selected Hormones and Frequently Measured Hormone Precursors and Cytokines

Endocrine Organ and Hormone	Chemical Nature of Hormone	Major Sites of Action	Principal Actions
Hypothalamus			
Thyrotropin-releasing hormone (TRH)	Peptide (3 aa, Glu-His-Pro)[a]	Anterior pituitary	Release of TSH and prolactin (PRL)
Gonadotropin-releasing hormone (Gn-RH) or luteinizing hormone-releasing hormone (LH-RH)	Peptide (10 aa)	Anterior pituitary	Release of LH and FSH
Corticotropin-releasing hormone (CRH)	Peptide (41 aa)	Anterior pituitary	Release of ACTH and β-lipotropic hormone (LPH)
Growth hormone-releasing hormone (GH-RH)	Peptides (40, 44 aa)	Anterior pituitary	Release of growth hormone (GH)
Somatostatin[b] (SS) or growth hormone-inhibiting hormone (GH-IH)	Peptides (14 and 28 aa)	Anterior pituitary	Suppression of secretion of many hormones (e.g., GH, TSH, gastrin, vasoactive intestinal polypeptide [VIP], gastric inhibitory polypeptide [GIP], secretin, motilin, glucagon, and insulin)
Prolactin-releasing peptide	Peptide (20 aa)	Anterior pituitary	Release of PRL
Prolactin releasing/inhibiting factor	Dopamine	Anterior pituitary	Suppression of synthesis and secretion of PRL
Anterior Pituitary Lobe			
Thyrotropin or thyroid-stimulating hormone (TSH)	Glycoprotein heterodimer[c] (α, 92 aa; β, 112 aa)	Thyroid gland	Stimulation of thyroid hormone formation and secretion
Follicle-stimulating hormone (FSH)	Glycoprotein, heterodimer[c] (α, 92 aa; β, 117 aa)	Ovary	Growth of follicles with LH, secretion of estrogens, and ovulation
		Testis	Development of seminiferous tubules; spermatogenesis
Luteinizing hormone (LH)	Glycoprotein, heterodimer[c] (α, 92 aa; β, 121 aa)	Ovary	Ovulation; formation of corpora lutea; secretion of progesterone
		Testis	Stimulation of interstitial tissue; secretion of androgens
PRL	Peptide (199 aa)	Mammary gland	Proliferation of mammary gland; initiation of milk secretion; antagonist of insulin action
Growth hormone (GH) or somatotropin	Peptide (191 aa)	Liver	Production of IGF-I (promoting growth)
		Liver and peripheral tissues	Antiinsulin and anabolic effects
Corticotropin or adrenocorticotropin (ACTH)	Peptide (39 aa)	Adrenal cortex	Stimulation of adrenocortical steroid formation and secretion
β-Endorphin (β-END)[bh]	Peptide (31 aa)	Brain	Endogenous opiate; raising of pain threshold and influence on extrapyramidal motor activity

TABLE 28-1 Selected Hormones and Frequently Measured Hormone Precursors and Cytokines—*Continued*

Endocrine Organ and Hormone	Chemical Nature of Hormone	Major Sites of Action	Principal Actions
Anterior Pituitary Lobe—Cont'd			
α-Melanocyte-stimulating hormone (α-MSH)	Peptide (13 aa)	Skin	Dispersion of pigment granules, darkening of skin
Leu-enkephalin (LEK)[b,h] and met-enkephalin (MEK)[b,h]	Peptide (5 aa)	Brain	Same as β-endorphin
Posterior Pituitary Lobe			
Vasopressin or ADH	Peptide (9 aa)	Arterioles Renal tubules	Elevation of blood pressure; water reabsorption
Oxytocin	Peptide (9 aa)	Smooth muscles (uterus, mammary gland)	Contraction; action in parturition and in sperm transport; ejection of milk
Pineal Gland			
Serotonin or 5-hydroxytryptamine (5-HT)	Indoleamine	Cardiovascular, respiratory, and gastrointestinal systems; brain	Neurotransmitter; stimulation or inhibition of various smooth muscles and nerves
Melatonin	Indoleamine	Hypothalamus	Suppression of gonadotropin and GH secretion; induction of sleep
Thyroid Gland			
Thyroxine (T_4) and triiodothyronine (T_3)	Iodoamino acids	General body tissue	Stimulation of oxygen consumption and metabolic rate of tissue
Calcitonin or thyrocalcitonin	Peptide (32 aa)	Skeleton	Uncertain in humans
Parathyroid Gland			
Parathyroid hormone (PTH) or parathyrin	Peptide (84 aa)	Kidney	Increased calcium reabsorption, inhibited phosphate reabsorption; increased production of 1,25-dihydroxycholecalciferol
		Skeleton	Increased bone resorption
Adrenal Cortex			
Aldosterone	Steroid	Kidney	Salt and water balance
Androstenedione[d]	Steroid	Hormone precursor	Converted to estrogens and testosterone
Cortisol	Steroid	Many	Metabolism of carbohydrates, proteins, and fats; antiinflammatory effects; others
Dehydroepiandrosterone (DHEA) and dehydroepiandrostenedione sulfate (DHEAS)	Steroids	Hormone precursors	Converted to estrogens and testosterone
17-Hydroxyprogesterone	Steroid	Hormone precursor	Converted to cortisol

Continued.

TABLE 28-1 Selected Hormones and Frequently Measured Hormone Precursors and Cytokines—*Continued*

Endocrine Organ and Hormone	Chemical Nature of Hormone	Major Sites of Action	Principal Actions
Adrenal Medulla			
Norepinephrine and epinephrine	Aromatic amines	Sympathetic receptors	Stimulation of sympathetic nervous system
Epinephrine		Liver and muscle, adipose tissue	Glycogenolysis Lipolysis
Ovary			
Activin A	Peptides[e] 2 β_A subunits	Pituitary, ovarian follicle	Stimulates release of FSH; enhances FSH action; inhibits androgen production by theca cells
Activin B	Peptides[e] 2 β_B subunits beta	See activin A above	See activin A above
DHEA and DHEAS	Steroids	Hormone precursors	Converted to androstenedione
Estrogens	Phenolic steroids	Female accessory sex organs	Development of secondary sex characteristics
		Bone	Control of skeletal maturation et al
Follistatin	Peptides (288 aa, 315 aa)	Pituitary, ovarian follicles	Inhibits FSH synthesis and secretion by binding activin
Inhibin A	Peptide (α subunit and β_A subunit)	Hypothalamus, ovarian follicle	Inhibits FSH secretion; stimulates theca cell androgen production
Inhibin B	Peptide (α subunit and β_B subunit)	See inhibin A above	See inhibin A above
Progesterone	Steroid	Female accessory reproductive structure	Preparation of the uterus for ovum implantation, maintenance of pregnancy
Relaxin	Peptide[f]	Uterus	Inhibition of myometrial contraction
Testis			
Inhibin B	See above	Anterior pituitary, hypothalamus	Control of LH and FSH secretion
Testosterone	Steroid	Male accessory sex organs	Development of secondary sex characteristics, maturation, and normal function
Placenta			
Estrogens	See above	See above	See above
Progesterone	See above	See above	See above
Relaxin	See above	See above	See above
Chorionic gonadotropin (CG) or choriogonadotropin	Glycoprotein, heterodimer[c] (α, 92 aa; β, 145 aa)	Same as LH	Same as LH; prolongation of corpus luteal function
Placental growth hormone (GH-V)	Peptides (22 & 26 kD)	Same as GH	Same as GH
Chorionic somatomammotropin (CS) or placental lactogen (PL)	Peptide (191 aa)	Same as PRL	Same as PRL

TABLE 28-1 Selected Hormones and Frequently Measured Hormone Precursors and Cytokines—*Continued*

Endocrine Organ and Hormone	Chemical Nature of Hormone	Major Sites of Action	Principal Actions
Pancreas			
Amylin	Peptide (37 aa)	Pancreas	Inhibits glucagon and insulin secretion
Glucagon	Peptide (29 aa)	Liver	Glycogenolysis
Insulin	Peptide[g]	Liver, fat, muscle	Regulation of carbohydrate metabolism; lipogenesis
Pancreatic polypeptide (PP)	Peptide (36 aa)	Gastrointestinal tract	Increased gut motility and gastric emptying; inhibition of gallbladder contraction
Somatostatin (SS)	Peptide (14 aa)	Pancreas	Inhibition of secretion of insulin, glucagon
Gastrointestinal Tract			
Gastrin[h]	Peptide (17 aa)	Stomach	Secretion of gastric acid, gastric mucosal growth
Ghrelin[h] (GHRP)	Peptide (28 aa)	Anterior pituitary	Secretion of GH
Secretin	Peptide (27 aa)	Pancreas	Secretion of pancreatic bicarbonate and digestive enzymes
Cholecystokinin-pancreozymin (CCK-PZ)[h]	Peptide (33 aa)	Gallbladder and pancreas	Stimulation of gallbladder contraction and secretion of pancreatic enzymes
Motilin	Peptide (22 aa)	Gastrointestinal tract	Stimulation of gastrointestinal motility
VIP[h]	Peptide (28 aa)	Gastrointestinal tract	Neurotransmitter; relaxation of smooth muscles of gut and of circulation; increased release of hormones and secretion of water and electrolytes from pancreas and gut
GIP	Peptide (42 aa)	Gastrointestinal tract	Inhibition of gastric secretion and motility; increase of insulin secretion
Bombesin[h]	Peptide (14 aa)	Gastrointestinal tract	Stimulation of release of various hormones and pancreatic enzymes, smooth muscle contractions and hypothermia, changes in cardiovascular and renal function
Neurotensin[h]	Peptide (13 aa)	Gastrointestinal tract and hypothalamus	Uncertain
Substance P (SP)[h]	Peptide (11 aa)	Gastrointestinal tract and brain	Sensory neurotransmitter, analgesic; increase in contraction of gastrointestinal smooth muscle; potent vasoactive hormone; promotion of salivation, increased release of histamine

Continued.

TABLE 28-1 Selected Hormones and Frequently Measured Hormone Precursors and Cytokines—*Continued*

Endocrine Organ and Hormone	Chemical Nature of Hormone	Major Sites of Action	Principal Actions
Kidney			
1,25-$(OH)_2$ cholecalciferol	Sterol	Intestine	Facilitation of calcium and phosphorus absorption; increase in bone resorption in conjunction with PTH
		Bone	
		Kidney	Increase in reabsorption of filtered calcium
Erythropoietin	Peptide (165 aa)	Bone marrow	Stimulation of red cell formation
Renin-angiotensin-aldosterone system	Peptides (renin, 297 aa; Ang I, 10 aa; Ang II, 8 aa, produced from Ang I by angiotensin converting enzyme)	Renin (from kidney) catalyzes hydrolysis of angiotensinogen (from liver, 485 aa) to ang I in the intravascular space	Ang II increases blood pressure and stimulates secretion of aldosterone (see adrenal)
Liver			
IGF-I, formerly called somatomedin	Peptide (70 aa)	Most cells	Stimulation of cellular and linear growth
IGF-II	Peptide (67 aa)	Most cells	Insulin-like activity
Thymus			
Thymosin and thymopoietin	Peptides (28 and 49 aa)	Lymphocytes	Maturation of T lymphocytes
Heart			
Atrial natriuretic peptide (ANP, Atriopeptin)	Peptide with an intrachain disulfide bond (28 aa)	Vascular, renal, and adrenal tissues	Regulation of blood volume and blood pressure
B-type natriuretic peptide (BNP)	Peptide with an intrachain disulfide bond (32 aa)	Vascular, renal, and adrenal tissues	Regulation of blood volume and blood pressure
Adipose Tissue			
Adiponectin	Peptide oligomers of 30 kD subunits	Muscle	Increases fatty acid oxidation
		Liver	Suppresses glucose formation
Leptin	Peptide (167 aa)	Hypothalamus	Inhibition of appetite, stimulation of metabolism
Resistin	Peptide (94 aa)	Liver	Insulin resistance
Multiple Cell Types			
Estrogens	See above	See above	See above
Galanin	Peptide (30 aa)	Brain, pancreas, gastrointestinal (GI) tract	Regulates food intake, memory, and cognition; inhibits endocrine and exocrine secretions of pancreas; delays gastric emptying; prolongs colonic transport times

TABLE 28-1 Selected Hormones and Frequently Measured Hormone Precursors and Cytokines—*Continued*

Endocrine Organ and Hormone	Chemical Nature of Hormone	Major Sites of Action	Principal Actions
Multiple Cell Types—Cont'd			
Parathyroid hormone-related peptide (PTH-RP)	Peptides (139, 141, 173 aa)	Kidney, bone	Physiological function conjectural; PTH-like actions; tumor marker
Growth factors (e.g., epidermal growth factor, fibroblast growth factor, transforming growth factor family, platelet-derived growth factor, nerve growth factors)	Peptides	Many	Stimulation of cellular growth
Monocytes/Lymphocytes/Macrophages			
Cytokines (e.g., interleukins 1-18, tumor necrosis factor, interferons)	Peptides	Many	Stimulation or inhibition of cellular growth; other

[a] *aa,* Amino acid residues.
[b] Also produced by gastrointestinal tract and pancreas.
[c] Glycoprotein hormones composed of two dissimilar peptides. The α-chains are similar in structure or identical; the β-chains differ among hormones and confer specificity.
[d] Androstenedione is also produced in the ovary and testis.
[e] Each activin and inhibin is found in multiple forms.
[f] Two chains linked by two disulfide bonds: α, 24 aa; β, 29 aa.
[g] Two chains linked by two disulfide bonds: α, 21 aa; β, 30 aa.
[h] Also produced in the brain.

Growth and Development

Normal growth and development of the whole human organism is dependent on the complex integrative function of many hormones including gonadal steroids (estrogen and androgen), growth hormone, cortisol, and thyroxine. Several pituitary hormones are responsible specifically for the growth and development of endocrine glands themselves and thus are responsible for control of synthesis and secretion of other hormones. Those other hormones can provide negative feedback on secretion of the pituitary hormones. Other regulators of the secretion of the pituitary hormones include circadian rhythms and a hypothalamic pulse generator that controls the pulsatile secretion of gonadotropins. Examples of hormones of the anterior pituitary gland include the following:

- Gonadotropins (luteinizing hormone [LH] and follicle-stimulating hormone [FSH]) that regulate the development, growth, and function of the ovary and testis (see Chapter 53). The ovarian and testicular hormones in turn regulate pubertal growth; the development and maintenance of secondary sex characteristics; the growth, development, and maintenance of the skeleton and muscles; and distribution of body fat.
- ACTH that regulates the growth of the adrenal glands and the synthesis and secretion of adrenal gland hormones (see Chapters 50 and 51).
- Thyroid-stimulating hormone (TSH) that regulates the growth of the thyroid gland and the iodination of amino acids to produce the thyroid hormones triiodothyronine and thyroxine (see Chapter 52).[1]

Homeostatic Control of Metabolic Pathways

The metabolic pathways under hormonal control are diverse and complex. The following important examples illustrate the feedback control of hormone secretion, which is critical for homeostasis:

- Regulation of blood glucose: In response to a glucose load, there is prompt release of insulin from the pancreas, which regulates the dispersal of glucose into cells (fat, muscle, liver, and brain) for the metabolism necessary to produce energy from glucose (see Chapter 25). As circulating glucose concentrations thus return to preload levels, insulin secretion slows. A number of counter-regulatory hormones come into play to further regulate this process to ensure that blood glucose levels do not become too low. These include glucagon, cortisol, epinephrine, and growth hormone.
- Regulation of serum calcium (see Chapter 49): The calcium-sensing receptor (CaSR) on the parathyroid gland recognizes the ambient concentration of ionized calcium, which in turn regulates synthesis and secretion of PTH. When ionized calcium concentrations fall

(so imperceptibly that most analytical methods could not detect the change), PTH synthesis and secretion are stimulated. This additional PTH will attempt to restore serum ionized calcium by enhancing renal tubular reabsorption of calcium and also calcium efflux from the skeleton. PTH also catalyzes the synthesis of the renal hormone calcitriol (1,25-dihydroxycholecalciferol), which acts on the gut to increase intestinal absorption of calcium. These very rapid responses of PTH and calcitriol quickly restore ionized calcium concentration to a level where the CaSR is no longer activated and both PTH and calcitriol synthesis and secretion return to basal levels.

- Water and electrolyte metabolism is regulated by aldosterone from the adrenal gland, renin from the kidney, and vasopressin (antidiuretic hormone [ADH]) from the posterior pituitary gland (see Chapters 45 and 46).

Regulation of the Production, Use, and Storage of Energy

Under normal conditions, regulation of energy production, use, and storage is under tight hormonal control. Under conditions of changing demands that require more energy (e.g., exercise, starvation, infection or trauma, and emotional stress), many hormones are up regulated to control not only circulating levels of nutrients but also the metabolism of these nutrients into necessary energy. This very complex activity, which may involve hormones from different organs as already alluded to in the preceding section, is also under neurological control, with a number of neuroendocrine hormones participating actively in this integrative metabolic process, which affects most organs in the body and modulates, for example, heart rate, sweating, fertility, and reproduction.

ROLE OF HORMONE RECEPTORS

The "unique" or specific action of a hormone on its target tissue is a function of the interaction between the hormone and its receptor. As discussed above, there are several types of hormone-receptor interaction.[3,5,8,17] The hormone-receptor complex provides the very high specificity of the action of the hormone, allowing the target tissue to accumulate the hormone from among all the molecules to which it is exposed. This is essential since hormones generally circulate in picomolar or nanomolar concentrations (10^{-9} to 10^{-12} mol/L).

Hormone receptors may be on the cell surface or intracellular within the cytoplasm or nucleus.

Cell-Surface Receptors

Peptide hormones bind to cell-surface receptors and the conformational change resulting from this binding activates an effector system, which is in turn responsible for the downstream actions of the hormone (Figure 28-1).[11,12] For most peptide hormones, the intracellular effector that is activated

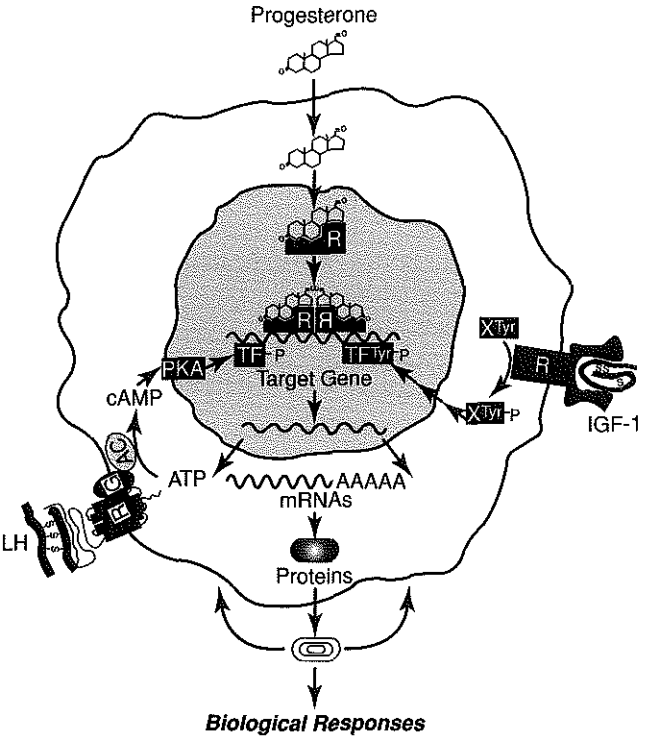

Figure 28-1 Hormonal signaling by cell-surface and intracellular receptors. The receptors for the water-soluble polypeptide hormones, LH, and insulin-like growth factor (IGF)-I, are integral membrane proteins located at the cell surface. They bind the hormone using extracellular sequences and transduce a signal by the generation of second messengers, cAMP for the LH receptor, and tyrosine-phosphorylated substrates for the IGF-I receptor. Although effects on gene expression are indicated, direct effects on cellular proteins (e.g., ion channels), are also observed. In contrast, the receptor for the lipophilic steroid hormone progesterone resides in the cell nucleus. It binds the hormone, and becomes activated and capable of directly modulating target gene transcription. *Tf*, Transcription factor; *R*, receptor molecule. *(From Conn PM, Melmed S. Textbook of endocrinology. Towanta NJ: Humana Press; 1997.)*

by the hormone-receptor interaction is a specific G-protein (guanyl-nucleotide-binding protein)[4,10,13,18] and the receptors are called G-protein–coupled receptors (GPCR, Figure 28-2). GCPRs are heptahelical molecules with seven membrane-spanning domains. The amino terminus is extracellular and the carboxy terminus is intracellular. The major structural classes of GPCRs have been identified, each containing receptors for specific subsets of hormones (Figure 28-3). Group I is the largest group containing receptors for many peptide hormones and catecholamines. Group II contains receptors for the family of gastrointestinal hormones (secretin, glucagons, and vasoactive intestinal polypeptide). Group III contains the CaSR and the glutamate receptor. Stimulation of a G-protein initiates the intracellular processes of signal transduction that characterize the specific action of the hormone. G-proteins are composed of α, β, and γ subunits and are classified according to the α subunit, of

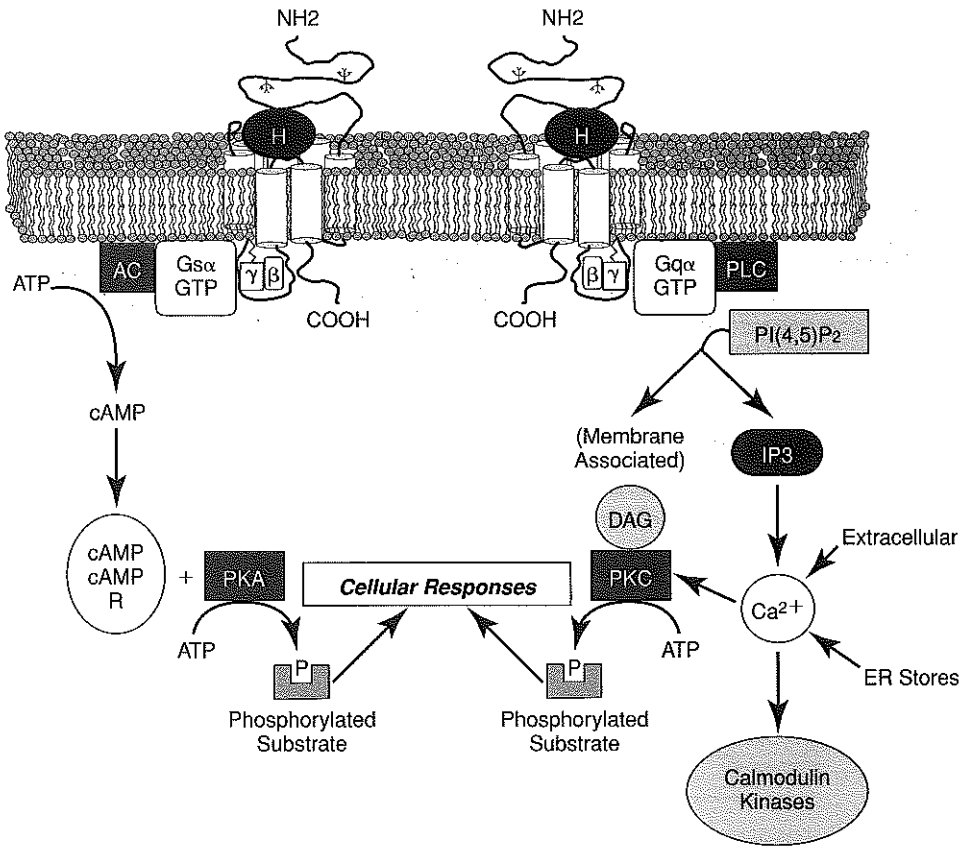

Figure 28-2 Signal transduction by cell-surface receptors that are coupled to G-proteins. Two seven-transmembrane domains, coupled to different G-proteins (G_S, and G_q) are shown. Activation of G_S leads to stimulation of the effector enzyme adenylate cyclase and the production of a cAMP second messenger, causing the activation of protein kinase A (PKA) and the initiation of potential phosphorylation cascades. Activation of G_q leads to stimulation of the effector enzyme phospholipase C-β and the production of IP3 and diacylglycerol (DAG) second messengers, one effect of which is to activate protein kinase C (PKC) and initiate a potential phosphorylation cascade. *(From Conn PM, Melmed S, eds. Textbook of endocrinology. Towanta NJ: Humana Press; 1997.)*

which 20 have been identified to date (Figure 28-3). G-proteins may stimulate adenylate cyclase (G_s type of G-proteins) or inhibit adenylate cyclase (G_i type). The many classes of GPRCs and G-proteins briefly described in this section provide some beginning insight into the mechanisms responsible for the specificity of hormone action. Some nonpeptide hormones also use cell-surface receptors.

Intracellular Receptors

Lipid-soluble hormones are transported in plasma bound to carrier proteins with only a small fraction of the hormone being in the free or unbound state. The free hormone enters the cell via passive diffusion and binds to intracellular receptors in the cytoplasm or, more often, the nucleus (Figure 28-1). These receptors are characterized by a hormone-binding domain, a deoxyribonucleic acid (DNA)–binding domain, and an amino-terminal variable domain. Just as the interaction of protein or polypeptide hormones with cell-surface receptors changes the conformation of the receptor protein, the binding of a lipid-soluble hormone with its specific hormone-binding domain on the intracellular receptor changes the molecular conformation of the intracellular receptor. This conformational change, or activation of the receptor, enables the hormone-receptor complex to bind to specific regulatory DNA sequences of a target gene, permitting control of specific gene expression (Figure 28-2).[7]

POSTRECEPTOR ACTIONS OF HORMONES

Cellsurface and intracellular receptors have different postreceptor actions.

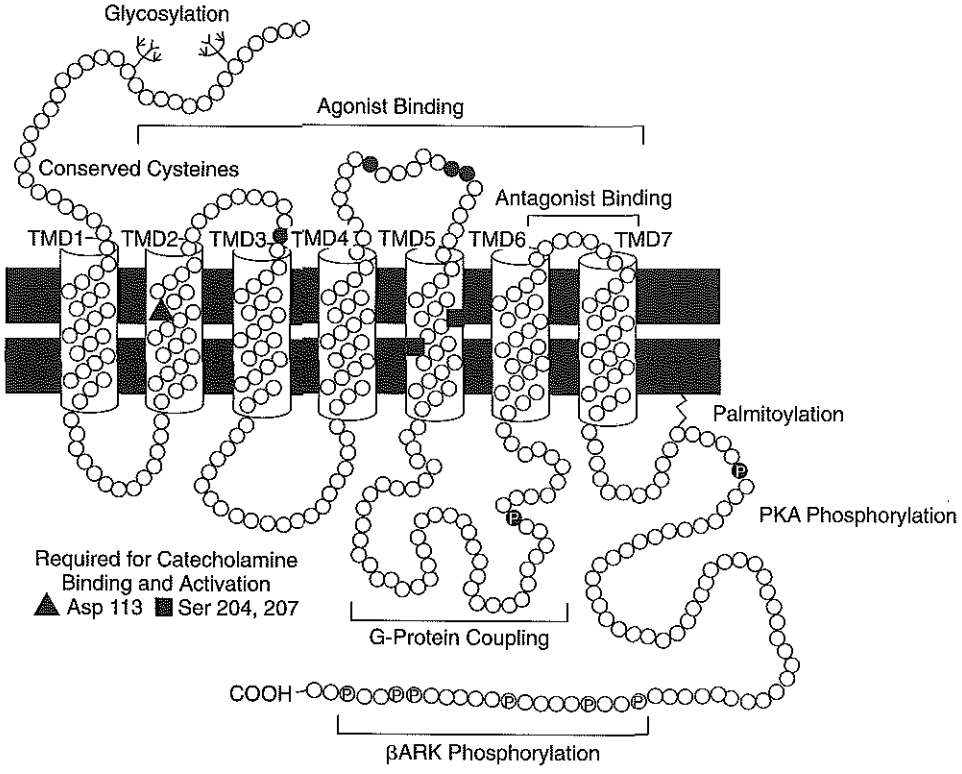
Cell-Surface Receptors

Once GPCRs are occupied by a hormone, the G-protein subunits begin a cascade of activation of specific enzymes that generate molecules that serve as second messengers to effect the hormone response. The best known of these are adenylyl cyclase, which generates cyclic adenosine monophosphate (cAMP), and phospholipase C, which generates both

G Protein-Coupled Receptor Superfamily

Family A:	*Receptors Related to Rhodopsin and the β-Adrenergic Receptor*
Group I:	Olfactory, Adenosine, Melanocortin Rs
Group II:	Adrenergic, Muscarinic, Serotonin, DA Rs
Group III:	Neuropeptide Rs and Vertebrate Opsins
Group IV:	Bradykinin R and Invertebrate Opsins
Group V:	Peptide and GP Hormone, Chemokine Rs
Group VI:	Melatonin and Orphan Rs

Family B:	*Receptors Related to the Calcitonin and Parathyroid Hormone Receptors*
Group I:	Calcitonin, Calcitonin-like, CRF Rs
Group II:	PTH and PTHrP Rs
Group III:	Glucagon, Secretin, VIP, GHRH Rs



Family C:	*Receptors Related to the Metabotropic Glutamate Receptors*
Group I:	Metabotropic Glutamate Rs
Group II:	Extracellular Calcium Ion Sensor Rs

Family D:	*Receptors Related to the STE2 Pheromone Receptor*
Group I:	Alpha Factor Pheromone Rs

Family E:	*Receptors Related to the STE3 Pheromone Receptor*
Group I:	A Factor Pheromone Rs

Family F:	*Receptors Related to the cAMP Receptor*
Group I:	Dictyostelium cAR1-4 Rs

A

B

Figure 28-3 Classification and basic architecture of cell-surface receptors that couple to G-proteins. Panel A lists the major families and groups of GPCRs. The mammalian receptors are confined to families A, B, and C. Family A is the largest and includes the diverse odorant receptors and prototypic GPCRs, such as rhodopsin and the β-adrenergic receptor. Panel B shows a schematic structure of one of the most extensively characterized GPCRs, the β-adrenergic receptor. Major structural features are indicated and are expanded on in the text. *(From Conn PM, Melmed S. eds. Textbook of endocrinology. Towanta NJ: Humana Press; 1997.)*

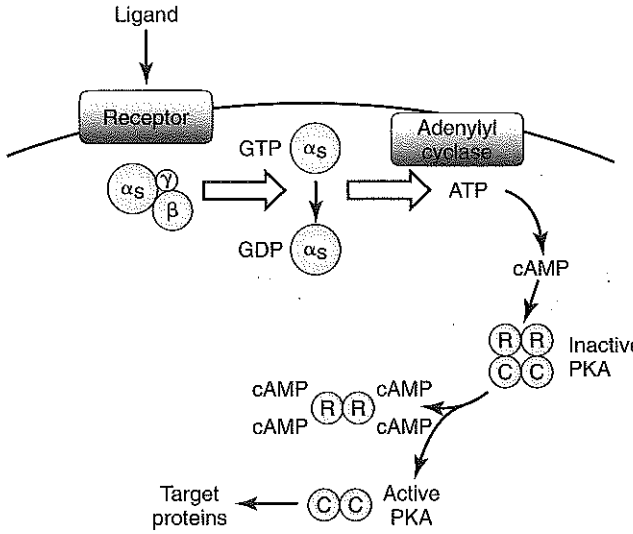


Figure 28-4 Signaling by G_S. *(From Conn PM, Melmed S, eds. Textbook of endocrinology. Towanta NJ: Humana Press; 1997.)*

inositol 1,4,5 trisphosphate (IP_3) and diacylglycerol. The production of second messengers, and the subsequent magnitude of the effect of the hormone, is a function of the amount of hormone bound to the GPRC. The binding of a small number of hormone molecules on the cell surface leads to the production of many molecules of the second messenger, thus amplifying the signal sent by the hormone (which can be thought of as the first messenger).

cAMP-dependent protein kinases are a family of enzymes that, in the presence of cAMP, phosphorylate a number of intracellular enzymes and other proteins to activate or inactivate the function of these enzymes and proteins thereby regulating their function. As a further means of regulating hormone action, these cAMP-dependent kinases consist of two catalytic and two regulatory subunits (Figure 28-4). The regulatory subunits exist as a dimer that can bind two molecules of cAMP, and the binding of cAMP releases the catalytic subunits, which are then activated as phosphorylating enzymes. When cAMP is removed from the regulatory subunit, this dimer is not able to associate two catalytic subunits and amplify the signal of the hormone.

Phospholipase C acts on inositol phospholipids within the cell membrane to produce IP_3, which opens up ion channels to facilitate entry of calcium into the cytoplasm where it acts as a messenger, and diacylglycerol, which modulates protorn kinase C activity.

The insulin receptor represents a somewhat different class of cell-surface receptors that contain intrinsic hormone-activated tyrosine kinase activity and do not otherwise involve a second messenger.[16] The insulin receptor is the prototype of this type of receptor and consists of two α and two β subunits joined by disulfide bridges. The extracellular, hormone-binding domains are the α subunits, and the β subunits are intracellular. They contain an ATP binding site and a catalytic kinase domain through which tyrosine kinase is activated immediately upon insulin binding to the receptor.

Since hormones largely serve a regulatory function, there are of necessity many self-limiting steps in the above processes. Without these self-limiting processes, hormone action would continue unabated. For cAMP, cessation of hormone action involves the inactivation of G-protein stimulation of adenylate cyclase by guanosine triphosphate (GTP)ase (Figure 28-5). In the absence of hormone interaction with the GPCR (basal or unstimulated state) G_s is bound to guanosine diphosphate (GDP). Once the hormone is bound to the receptor, GDP is released from G_s and replaced by GTP and the G_s-GTP complex activates adenylate cyclase. The G_s-GTP complex is inactivated by GTPase, restoring the G_s-GDP state, which cannot stimulate formation of cAMP until further hormone binding to the GPCR takes place. Within a few minutes (or less) of the hormone-GPCR interaction and the initiation of hormone action, the receptor is phosphorylated by protein kinase A and protein kinase C. This phosphorylation of the hormone receptor permits internalization of the complex from the cell surface into the cytoplasm where dephosphorylation occurs, permitting degradation of the hormone and recycling of the GPCR to its original transmembrane location, awaiting coupling with more hormone.

Intracellular Receptors

As noted, lipid-soluble hormones bind to the hormone-binding domain of cytosolic or nuclear receptors.[11,12] This results in a conformational change that enables the hormone-receptor complex to bind to specific regulatory DNA sequences in the 5′ end of the target gene.[7] The binding specificity of the (hormone-bound) receptor for specific regions of the DNA of the target gene is determined by zinc

finger structures in the receptor's DNA-binding domain. It is the binding of the hormone-receptor complex to DNA regulatory elements that either enhances or represses gene transcription. The messenger ribonucleic acid (RNA) that is either enhanced or diminished by the hormone-receptor binding to the target gene regulates the synthesis of specific proteins that mediate the hormone's physiological actions. The system is further regulated by the presence or absence of co-activators or co-repressors of gene expression. In addition, many actions of hormones that bind to intracellular receptors are rapid and do not depend on synthesis of protein, suggesting that these hormone-receptor complexes exert actions by mechanisms different from binding to DNA.

From these descriptions, one can begin to deduce both the complexity and specificity of hormone action both in terms of an "on and/or off" concept and in terms of an "effect-size" concept.

CLINICAL DISORDERS OF HORMONES

Although several chapters of this textbook detail a variety of endocrine disorders, a brief introduction is appropriate here. In general, endocrine diseases result from either a deficiency or an excess of a single hormone or several hormones, or from resistance to the action of hormones. Hormone deficiency can be congenital or acquired and hormone excess can be from endogenous overproduction (from within the body) or exogenous overmedication. Hormone resistance can occur at several levels, but can most simply be characterized as receptor mediated, postreceptor mediated, or at the level of the target tissue. The clinical manifestations will depend on the hormone system affected and the type of abnormality.

Diabetes mellitus (DM) is an example of an endocrine disorder; it is the most common endocrine disorder in the United States (see Chapter 25). It is classified as either type 1 or type 2. DM type 1 results from a failure of the pancreas to secrete insulin even though the pancreas is otherwise normal. Type 2 is the most common form of DM and results from end-organ resistance to the action of insulin that, in this case, is secreted from the pancreas in abundant amounts and circulates at high concentrations. Secondary DM occurs when a nonendocrine disease, such as pancreatitis, destroys the pancreas including the insulin secreting cells. The biochemical hallmark of DM is hyperglycemia.

In contrast to diabetes, there are uncommon, insulin-producing tumors of the pancreas (insulinomas) in which the production of insulin is not regulated by the blood glucose concentration and the biochemical hallmark of the tumors is hypoglycemia. Thus hyperglycemia can be present when there is either insulin deficiency or insulin excess, and insulin excess can accompany both hyperglycemia and hypoglycemia. This simple illustration underscores the homeostatic and/or regulating nature of the endocrine system.

MEASUREMENTS OF HORMONES AND RELATED ANALYTES

Hormones are measured by a variety of analytical techniques including bioassay, receptor assay, immunoassay, and instrumental techniques, such as mass spectrometry interfaced with either liquid or gas chromatography. A general overview of these techniques is given here. Analytical details for individual hormones using such techniques are found in the discussion of the individual hormones in their respective chapters.

Bioassay Techniques

Bioassays are based on observations of physiological responses specific for the hormone being measured. In vivo bioassays usually involve the injection of test materials (such as blood or urine from a patient) into suitably prepared animals; target gland responses, such as growth or steroidogenesis, are then measured. In vitro bioassays involve the incubation of tissue, membranes, dispersed cells, or permanent cell lines in a defined culture medium, with subsequent measurement of an appropriate hormone response. Most in vitro bioassays measure responses proximal or distal to a second messenger, such as stimulation of cAMP formation. Bioassays tend to be imprecise and are rarely necessary in clinical medicine.

Receptor-Based Assays

Receptor assays depend on the in vitro interaction of a hormone with its biological receptor. In this type of assay, unlabeled hormone displaces trace amounts of radioactively labeled hormone from receptor sites. A second approach is to measure a response, such as production of cAMP, when a test sample is added to a preparation that includes the receptor and necessary cofactors. In general, receptor assays are simpler to perform and have greater sensitivity than bioassays. Receptor assays also have an advantage over immunoassays in that they reflect the biological function of a hormone, namely the capacity to combine with specific receptor sites. By contrast, immunoassays may measure active hormone and inactive prohormone, hormone polymer, and metabolites when all share a common antigenic determinant or set of determinants. In general, receptor assays are not as sensitive as immunoassays, and enzymes in the biological specimen may degrade the receptor or destroy the labeled tracer. The added complexity and lability of receptor preparations also contribute to the limited application of these assays in the routine clinical laboratory.

Immunoassay Techniques

Immunoassays employing antibodies are widely used to quantify hormones (see Chapter 9). Currently, labeled-antibody (immunometric) assays with nonisotopic labels are the method of choice for measuring most hormones, especially peptides and proteins. Immunometric assays use saturating concentrations of two or more antibodies (often

monoclonal) that are prepared against different epitopes of the protein molecule. One of the two antibodies is usually attached to a solid phase separation system and extracts the hormone from the serum specimen. The second antibody is linked to a signal molecule, which is then measured. The resultant signal is used to quantify the bound hormone.

Instrumental Techniques

Mass spectrometers (see Chapter 7) coupled with gas and liquid chromatographs (see Chapter 6) are powerful qualitative and quantitative analytical tools that are widely used to measure hormones.[2,6,9,14] Technical advancements in mass spectrometry have resulted in the development of matrix-assisted laser desorption/ionization (MALDI) and electrospray ionization techniques that allow sequencing of peptides and mass determination of picomole quantities of analytes.

Compared with older methods, tandem mass spectrometry offers greater analytical sensitivity, accuracy, and speed, and may allow simultaneous determination of multiple hormones related to a clinical condition.[14]

CHAPTER 29

Catecholamines and Serotonin

Thomas G. Rosano, Ph.D., Graeme Eisenhofer, Ph.D., and Ronald J. Whitley, Ph.D.

Catecholamines and serotonin are biogenic amines that serve as transmitters of neuronal or hormonal signals in a wide range of physiological processes. Epinephrine, norepinephrine, and dopamine are naturally occurring catecholamines that play important roles as neurotransmitters in the central nervous system or as peripheral neurotransmitters and hormonal signals in the sympathoadrenal medullary system. Epinephrine is critical, along with norepinephrine and dopamine, in maintaining the body's homeostasis and in responding to acute and chronic stress, through an orchestration of cardiovascular, metabolic, glandular, and visceral organ activities. Serotonin also serves as a neurotransmitter in the central nervous system and a modulator of vascular and gastrointestinal functions in the periphery. Abnormal production of catecholamines or serotonin may occur in a number of neuroendocrine tumors where clinical signs and symptoms reflect the pharmacological properties of the secreted amines. Clinical measurement of the biogenic amines or their metabolites aids in tumor detection and monitoring, and analytical advances have produced sensitive and specific laboratory methods that are available for clinical practice. In this chapter, we provide an overview of important aspects of biochemistry, pathophysiology, and analytical methodology for clinical assessment of catecholamines, serotonin, and their metabolites.

CHEMICAL STRUCTURE

Chemical structures of catecholamines produced naturally in humans are shown in Figure 29-1. *Epinephrine* (adrenaline), *norepinephrine* (noradrenaline), and *dopamine* are phenylethylamines with hydroxylation on positions three and four of the benzene ring and with an ethylamine moiety on position one. Hydroxyl and methyl substitution on the ethylamine side chain distinguishes the individual catecholamines both in structure and function. The catecholamines demonstrate varying degrees of alkaline instability in biological fluids and their dihydroxybenzene or catechol structure is sensitive to oxidative formation of quinones in the presence of air and light. A number of pharmaceutical and designer drugs with the basic phenylethylamine structure, but lacking dihydroxylation, also have effects on the sympathetic nervous system and are called sympathomimetic agents.

Serotonin with its indoleamine structure, as also shown in Figure 29-1, is distinct from the catecholamines but is also an important naturally occurring biogenic amine. Serotonin is produced widely in animal and plant kingdoms and is structurally related to melatonin, the principal indoleamine produced by the pineal gland. A number of natural or synthetic congeners of serotonin have biological effects ranging from cerebral vasoconstrictors (e.g., sumatriptan) to hallucinogens (e.g., *N,N*-dimethyltryptamine).

Although structurally distinct, the catecholamines and serotonin have related biometabolism, as described in the next section, and each serves as an important monoamine neurotransmitter or neurohormone in health and disease.

BIOSYNTHESIS, RELEASE, AND METABOLISM

The catecholamines and serotonin share similar pathways of biosynthesis and metabolism, including in some steps, the same enzymes. Catecholamines and serotonin are sequestered and stored in vesicular granules from where they are released into the extracellular environment by calcium-dependent exocytosis. Termination of the physiological effects of both the catecholamines and serotonin is dependent on active uptake processes, facilitated by specific

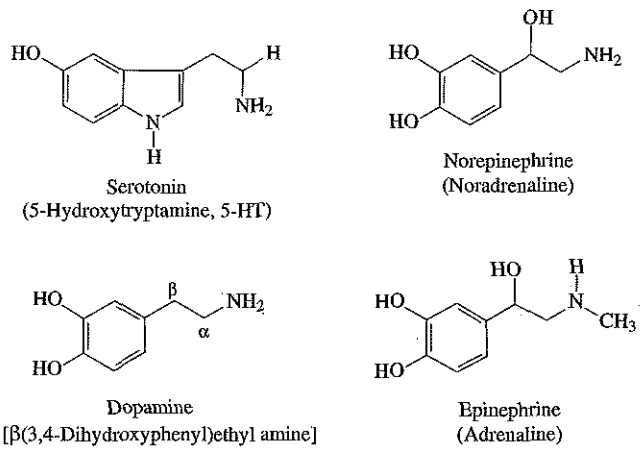

Figure 29-1 Chemical structure of the catecholamines and serotonin.

plasma membrane transport proteins. Irreversible inactivation occurs after cellular uptake by metabolism, mainly by deamination and O-methylation for catecholamines, and by deamination for serotonin.

Biosynthesis

Catecholamines are synthesized from the amino acid tyrosine, and serotonin from tryptophan as shown in Figure 29-2. The rate-limiting step in catecholamine biosynthesis involves conversion of tyrosine to 3,4-dihydroxyphenylalanine (L-dopa) by the enzyme, tyrosine hydroxylase.[186] A related enzyme, tryptophan hydroxylase, catalyzes conversion of tryptophan to 5-hydroxytryptophan in the first step of serotonin synthesis.

Tissue sources of catecholamines are principally dependent on the presence of tyrosine hydroxylase, which is largely confined to dopaminergic and noradrenergic neurons of the central nervous system, and to sympathetic nerves and chromaffin cells of the adrenal medulla and paraganglia in the periphery. Similarly, sources of serotonin are largely dependent on the presence of tryptophan hydroxylase in central nervous system serotonergic neurons, the pineal gland, and some peripheral endocrine tissue, particularly enterochromaffin cells of the digestive tract. Platelets also contain large amounts of serotonin, but this is derived from serotonin synthesized in enterochromaffin cells of the gastrointestinal tract.[235]

Both tyrosine and tryptophan hydroxylases belong to a small family of monooxygenases, that also includes phenylalanine hydroxylase; all three enzymes require tetrahydrobiopterin as a substrate to drive the hydroxylation reaction.[74] Deficiencies in the enzymes responsible for formation and recycling of tetrahydrobiopterin result in variant forms of phenylketonuria and hyperphenylalaninemia characterized by low levels of monoamine neurotransmitters and severe neurological abnormalities.[132]

Conversion of L-dopa to dopamine and of 5-hydroxytryptophan to serotonin are both catalyzed by

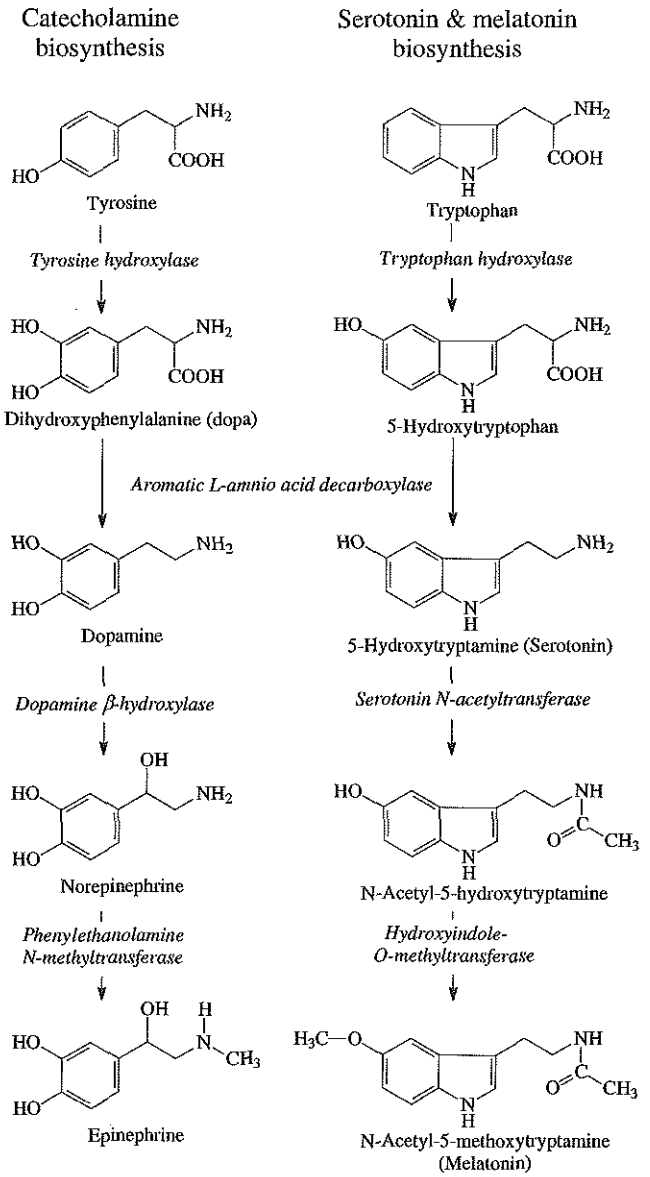

Figure 29-2 Biosynthesis of catecholamines and serotonin, and metabolism of serotonin to melatonin.

aromatic-L-amino acid decarboxylase (Figure 29-2), an enzyme with a wide tissue distribution and broad substrate specificity for aromatic amino acids. The enzyme requires pyridoxal-5-phosphate as a cofactor. The dopamine and serotonin formed in the cytoplasm by aromatic-L-amino acid decarboxylase are then transported into vesicular storage granules where the amines are available for exocytotic release as the principal neurotransmitters of central nervous system dopaminergic and serotonergic neurons.

The dopamine formed in noradrenergic neurons and chromaffin cells is further converted to norepinephrine by dopamine β-hydroxylase, a copper-containing enzyme that requires molecular oxygen and ascorbic acid for activity. The enzyme has a unique presence in vesicular storage granules, either bound to the vesicular membrane or present in the

soluble matrix core. The noradrenergic neurochemical phenotype of central noradrenergic neurons and peripheral sympathetic nerves depends on both translocation of dopamine into storage granules and the presence of dopamine β-hydroxylase.

The additional presence of phenylethanolamine *N*-methyltransferase in adrenal medullary chromaffin cells leads to further conversion of norepinephrine to epinephrine (Figure 29-2). Since phenylethanolamine *N*-methyltransferase is a cytosolic enzyme, this step depends on leakage of norepinephrine from vesicular storage granules into the cell cytoplasm and the transfer of a methyl group from *S*-adenosylmethionine to norepinephrine. Epinephrine is then translocated into chromaffin granules where the amine is stored, awaiting release.

Melatonin is synthesized from serotonin in the pineal gland by two highly specific enzymes, the first step catalyzed by serotonin-*N*-acetyltransferase and the second by hydroxyindole-*O*-methyltransferase. Synthesis of melatonin in the pineal gland is regulated by the 24-hour light-dark cycle, resulting in pronounced diurnal fluctuations in production, with higher melatonin levels at night associated with induction of sleep.

Conversion of tyrosine to L-dopa by tyrosine hydroxylase and of tryptophan to 5-hydroxytryptophan by tryptophan hydroxylase represents pivotal points for regulating synthesis and maintaining stores of catecholamines and serotonin in response to changes in monoamine turnover associated with variations in exocytotic release. Rapid activation of tyrosine hydroxylase is achieved by phosphorylation of serine residues at the regulatory domain, under the control of multiple Ca^{2+} and cyclic adenosine monophosphate (cAMP)–dependent pathways influenced by changes in nerve activity and actions of peptides and other coactivators.[185,265] Feedback inhibition by catecholamines provides a further mechanism for short-term regulation of enzyme activity. Long-term regulation involves induction of synthesis of the enzyme at the transcriptional level. Similar though less well understood mechanisms are involved in the regulation of tryptophan hydroxylase.[165] Synthesis of serotonin is also controlled by the availability of tryptophan precursor derived exclusively from the diet.[260] Tyrosine, in contrast, has dietary sources and is also formed by hydroxylation of phenylalanine.

Administration of catecholamine metabolic precursors and drugs that block catecholamine biosynthetic pathways has several therapeutic uses. Alpha-methyl-L-tyrosine or metyrosine (Demser) is an analog of tyrosine that inhibits tyrosine hydroxylase, thereby decreasing catecholamine stores. The drug is used to control high blood pressure in patients with pheochromocytoma, particularly those with extensive metastatic disease, or preoperatively in patients with large or highly active tumors. Alpha-methyl-L-dopa (Aldomet) is an analog of L-dopa and a prodrug that is converted to alpha-methyl-dopamine and alpha-methyl-norepinephrine. The antihypertensive actions of the agent appear to result from central nervous system–mediated inhibition of sympathetic outflow. L-dopa is used to treat Parkinson's disease and is usually co-administered with an inhibitor of peripheral L-aromatic amino acid decarboxylase, such as carbidopa or benserazide.

Storage and Release

Storage of catecholamines and serotonin in vesicular granules is facilitated by two vesicular monoamine transporters, both of which are expressed in endocrine cells and one only in neurons.[103] Both transporters have a wide specificity for different monoamine substrates.

The driving force for vesicular monoamine transport is provided by an adenosine triphosphate (ATP)–dependent vesicular membrane proton pump, which maintains an H^+ electrochemical gradient between cytoplasm and granule matrix.[224] Disruption of this gradient in situations of energy depletion and lowered intracellular pH, such as occurs with ischemia, anoxias or cyanide poisoning, result, in a rapid and massive loss of monoamines from storage vesicles into the neuronal cytoplasm.

Contrary to usual depictions, vesicular stores of catecholamines and serotonin do not exist in a static state until exocytotic release. Rather, vesicular stores of monoamines exist in a highly dynamic equilibrium with the surrounding cytoplasm, with passive outward leakage of monoamines into the cytoplasm counterbalanced by inward active transport under the control of vesicular monoamine transporters (Figure 29-3). The magnitude and highly dynamic nature of this process can be appreciated by consideration of the effects of the drug reserpine, which blocks the ability of vesicular monoamine transporters to move monoamines from the cytoplasm into vesicles. Leakage of monoamines from vesicles is then no longer counterbalanced by vesicular translocation and stores of monoamines are rapidly depleted.

Monoamines share the acid environment of the storage granule matrix with ATP, peptides, and proteins, the most well known of which are the chromogranins.[195] The chromogranins are ubiquitous components of secretory vesicles and their widespread presence among endocrine tissue has led to their measurement in plasma as useful albeit relatively nonspecific markers of neuroendocrine tumors, including pheochromocytomas and carcinoid tumors.[194]

Catecholamines are stored in several types of vesicular granules that differ in size and type of protein and peptide components. In rat and bovine adrenal medulla there are two populations of chromaffin cells with morphologically distinct vesicles that preferentially store either norepinephrine or epinephrine and that release the two catecholamines differentially in response to different stimuli.[249] In sympathetic nerves there are large and small dense core vesicles, the latter believed to be formed by retrieval of membranes of large dense core vesicles after exocytosis.[50]

The process of exocytosis occurs at specialized locations on nerve endings or sympathetic varicosities dictated by the

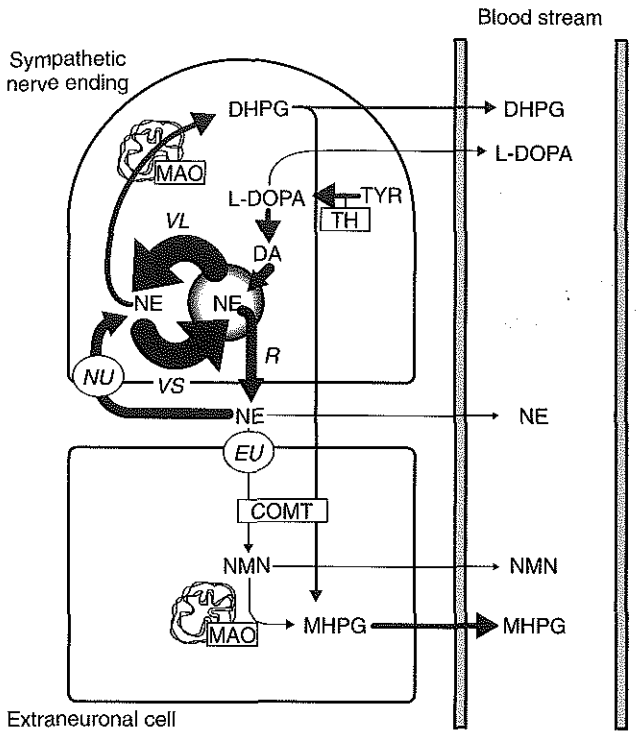

Figure 29-3 Schematic diagram illustrating the dynamics of synthesis, exocytotic release (R), neuronal reuptake (NU), extraneuronal uptake (EU), vesicular leakage (VL), vesicular sequestration (VS), and metabolism of norepinephrine (NE) in sympathetic nerve endings in relation to extraneuronal tissue and the bloodstream. Relative magnitudes of the various processes are reflected by the relative sizes of arrows. *TH,* Tyrosine hydroxylase; *MAO,* monoamine oxidase; *COMT,* catechol-*O*-methyltransferase; *TYR,* tyrosine; *L-dopa,* 3,4-dihydroxyphenylalanine; *DA,* dopamine; *DHPG,* 3,4-dihydroxyphenylglycol; *NMN,* normetanephrine; *MHPG,* 3-methoxy-4-hydroxyphenylglycol.

cell-surface expression of specialized docking proteins that interact with other proteins on the surface of secretory vesicles.[121] The process is stimulated by an influx of Ca^{2+}, which in neurons is primarily controlled by nerve impulse–mediated membrane depolarization, and in adrenal medullary cells by acetylcholine release from innervating splanchnic nerves. The wide range of voltage-, receptor-, G-protein–, and second messenger–operated Ca^{2+} channels provides numerous points for regulation of Ca^{2+}-triggered exocytosis. Consequently a variety of peptides, neurotransmitters, and humoral factors provide additional mechanisms for stimulation of exocytosis or may act to modulate nerve impulse–stimulated release of monoamines. Dopamine, norepinephrine, and serotonin also modulate their own release through occupation of autoreceptors. Regulation of monoamine release and synthesis is closely coordinated, thereby ensuring that there is appropriate replenishment of the amines lost because of exocytosis.[187]

Neuronal release of catecholamines and serotonin may also occur by calcium-independent nonexocytotic processes involving increased loss of monoamines from storage vesicles into the cytoplasm and reversal of the normal inward carrier-mediated transport to outward transport of monoamines into the extracellular environment. Examples of this process include the release of catecholamines induced by tyramine and amphetamine. Excessive release of catecholamines that accompanies hypoxic ischemia in part occurs by a similar mechanism.

Uptake and Metabolism

Since the enzymes responsible for metabolism of catecholamines have intracellular locations, the primary mechanism limiting the lifespan of catecholamines in the extracellular space is uptake by active transport, not metabolism by enzymes (Figure 29-3). Uptake is facilitated by transporters that belong to two large families of proteins with mainly neuronal or extraneuronal locations.[54] Neuronal uptake of monoamines involves the dopamine transporter at dopaminergic neurons, the norepinephrine transporter at noradrenergic neurons, and the serotonin transporter at serotonergic neurons. These same transporters are also present at some nonneuronal locations, including adrenal chromaffin cells, endothelial cells of the lungs, specialized cells of the gastrointestinal tract, and on some blood cells, such as platelets. However, most uptake of monoamines at nonneuronal locations is facilitated by a second set of proteins belonging to the organic cation transporter family. These latter transporters are expressed exclusively at extraneuronal locations and act on a broader range of substrates than the plasma membrane monoamine transporters expressed at neuronal locations.

The neuronal monoamine transporters provide the principal mechanism for rapid termination of the signal in neuronal transmission, whereas the transporters at extraneuronal locations are more important for limiting the spread of the signal and for clearance of catecholamines from the bloodstream. For the norepinephrine released by sympathetic nerves, about 90% is removed back into nerves by neuronal uptake, 5% is removed by extraneuronal uptake, and 5% escapes these processes to enter the bloodstream. In contrast, for the epinephrine released directly into the bloodstream from the adrenals, about 90% is removed by extraneuronal monoamine transport processes that are particularly important in the liver. The presence of these highly active transport processes means that monoamines are rapidly cleared from the bloodstream with a circulatory half-life of less than 2 minutes.

In addition to terminating the actions of released monoamines, the plasma membrane monoamine transporters present at neuronal locations function in sequence with vesicular monoamine transporters to recycle catecholamines for rerelease (Figure 29-3). Thus most of the norepinephrine released and recaptured by sympathetic nerves is sequestered back into storage vesicles, thereby substantially reducing the requirements for synthesis of new transmitter.

Plasma membrane monoamine transporters also function as part of metabolizing systems, requiring the additional

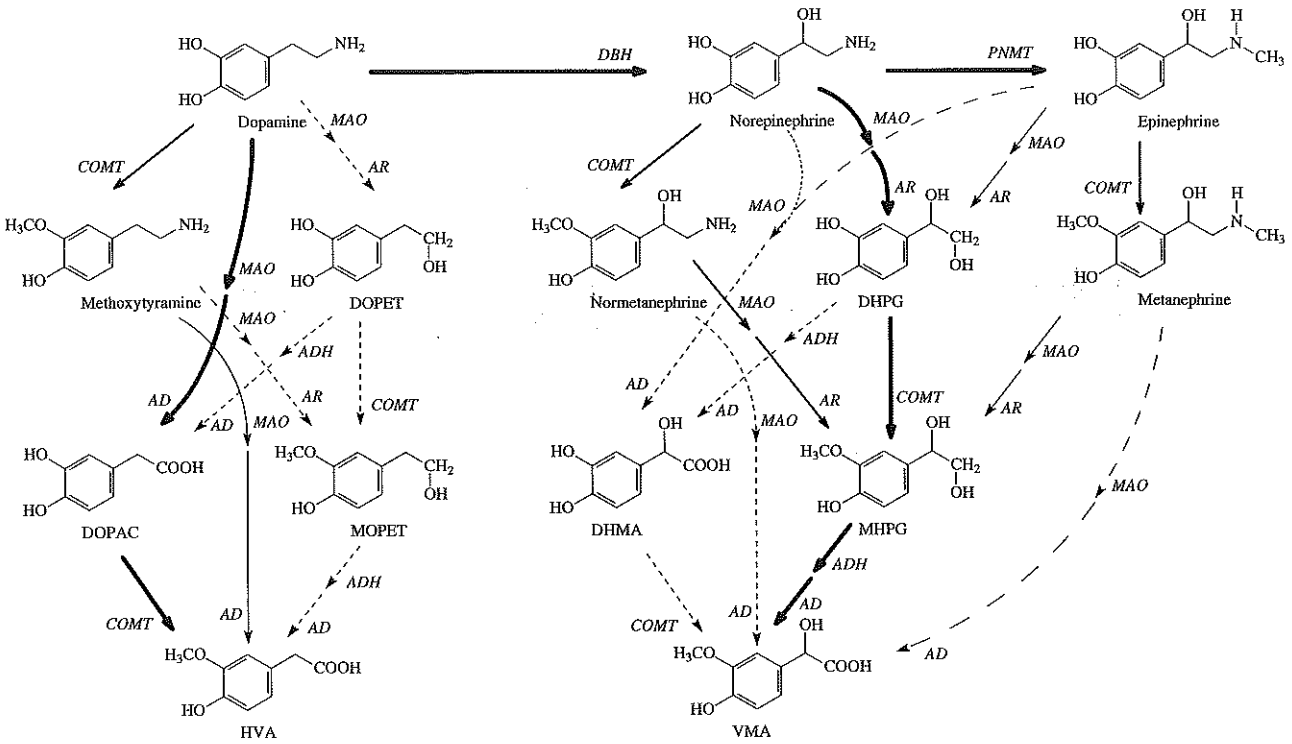

Figure 29-4 Pathways of metabolism of catecholamines. Enzymes responsible for each pathway are shown at the head of arrows. Solid arrows indicate the major pathways whereas dotted arrows indicate pathways of negligible importance. Pathways of sulfate conjugation—which are particularly important for metabolism of dopamine, normetanephrine, metanephrine, 3-methoxytyramine, and 3-methoxy-4-hydroxyphenylglycol—are not shown. *DBH*, Dopamine β-hydroxylase; *PNMT*, phenylethanolamine-*N*-methyltransferase; *MAO*, monoamine oxidase; *COMT*, catechol-*O*-methyltransferase; *AR*, aldose or aldehyde reductase; *AD*, aldehyde dehydrogenase; *ADH*, alcohol dehydrogenase; *DOPET*, 3,4-dihydroxyphenylethanol; *DOPAC*, 3,4-dihydroxyphenylacetic acid; *MOPET*, 3-methoxy-4-hydroxyphenylethanol; *HVA*, homovanillic acid; *DHPG*, 3,4-dihydroxyphenylglycol; *DHMA*, 3,4-dihydroxymandelic acid; *MHPG*, 3-methoxy-4-hydroxyphenylglycol; *VMA*, vanillylmandelic acid.

actions of enzymes for irreversible inactivation of the released amines. For both neuronal and extraneuronal metabolizing systems, inactivation of catecholamines and serotonin occurs in a series arrangement with uptake followed by metabolism.

Metabolism of catecholamines occurs by a multiplicity of pathways catalyzed by an array of enzymes resulting in a wide variety of metabolites (Figure 29-4).[60] Deamination of catecholamines by monoamine oxidase (MAO) yields reactive aldehyde intermediate metabolites that are further metabolized to either deaminated acids by aldehyde dehydrogenase, or to deaminated glycols by aldehyde or aldose reductase. The aldehyde intermediate formed from dopamine is a good substrate for aldehyde dehydrogenase, but not aldehyde or aldose reductase. In contrast, the aldehyde intermediate formed from the β-hydroxylated catecholamines norepinephrine and epinephrine is a good substrate for aldehyde or aldose reductase, but is a poor substrate for aldehyde dehydrogenase. Therefore norepinephrine and epinephrine are both preferentially deaminated to 3,4-dihydroxyphenylglycol (DHPG), the alcohol metabolite. Deamination to the deaminated acid metabolite, 3,4-dihydroxymandelic acid (DHMA), is not a favored pathway.

Catechol-*O*-methyltransferase (COMT) is responsible for the second major pathway of catecholamine metabolism, catalyzing *O*-methylation of dopamine to methoxytyramine, norepinephrine to normetanephrine, and epinephrine to metanephrine. COMT is not present in monoamine-producing neurons, which contain exclusively MAO, but is present along with MAO in most extraneuronal tissue. The membrane-bound isoform of COMT, which has high affinity for catecholamines, is especially abundant in adrenal chromaffin cells. As a result of the preceding and other differences in the expression of metabolizing enzymes, catecholamines produced at neuronal and adrenal medullary locations follow different neuronal and extraneuronal pathways of metabolism (Figure 29-5).

Neuronal pathways are quantitatively far more important than extraneuronal pathways for metabolism of the catecholamines synthesized at neuronal locations, such as the norepinephrine produced in sympathetic nerves. The

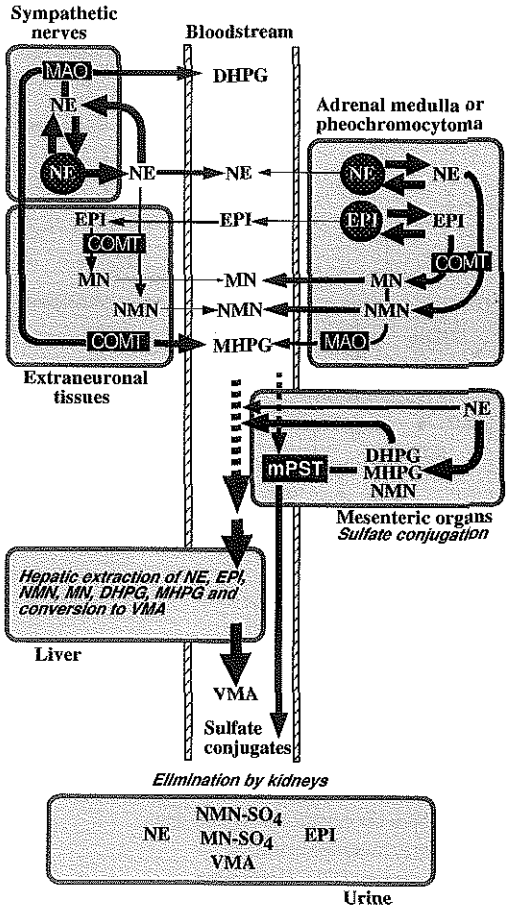

Figure 29-5 Schematic diagram illustrating the regional pathways of norepinephrine and epinephrine metabolism. Most norepinephrine is released and metabolized within sympathetic nerves, including up to one half produced in sympathetic nerves of mesenteric organs. Sulfate conjugation of catecholamines and catecholamine metabolites, particularly 3-methoxy-4-hydroxyphenylglycol (MHPG), occurs mainly in mesenteric organs, whereas production of vanillylmandelic acid (VMA) occurs mainly in the liver. *MAO*, Monoamine oxidase; *COMT*, catechol-*O*-methyltransferase; *SULT1A3*, sulfotransferase type 1A3; *NE*, norepinephrine; *EPI*, epinephrine; *NMN*, normetanephrine; *MN*, metanephrine; *DHPG*, 3,4-dihydroxyphenylglycol; *MHPG*, 3-methoxy-4-hydroxyphenylglycol; *VMA*, vanillylmandelic acid; *NMN-SO_4*, normetanephrine sulfate; *MN-SO_4*, metanephrine sulfate; *MHPG-SO_4*, 3-methoxy-4-hydroxyphenylglycol sulfate.

reasons for this are twofold. First, much more norepinephrine released by sympathetic nerves is removed by neuronal uptake than by extraneuronal uptake. Second, under resting conditions, much more of the norepinephrine metabolized intraneuronally is derived from transmitter leaking from storage vesicles than from transmitter recaptured after exocytotic release. Thus most of the norepinephrine produced in the body is metabolized initially to DHPG, mainly from transmitter deaminated intraneuronally after leakage from storage vesicles or after release and reuptake. Most circulating DHPG is derived from sympathetic nerves, with relatively small contributions from the brain (<5%) and adrenals (<7%).

DHPG is further *O*-methylated by COMT in nonneuronal tissue to 3-methoxy-4-hydroxyphenylglycol (MHPG), a metabolite also produced to a limited extent by deamination of normetanephrine and metanephrine (Figure 29-5). Compared with DHPG, the latter *O*-methylated metabolites are produced in small amounts, and only at extraneuronal locations, with the single largest source representing adrenal chromaffin cells, accounting for more than 90% of circulating metanephrine and 24% to 40% of circulating normetanephrine.[64] Within the adrenals, normetanephrine and metanephrine are produced similarly to DHPG in sympathetic nerves, from norepinephrine and epinephrine leaking from storage granules into the chromaffin cell cytoplasm.

The MHPG produced from DHPG and metanephrines is either sulfate conjugated or metabolized to vanillylmandelic acid (VMA) by the sequential actions of hepatic alcohol dehydrogenase and aldehyde dehydrogenase. At least 90% of the VMA formed in the body is produced in the liver, mainly from hepatic uptake and metabolism of circulating DHPG and MHPG.[22]

In contrast to production of VMA, production of homovanillic acid (HVA) from dopamine depends mainly on *O*-methylation of the deaminated metabolite of dopamine, 3,4-dihydroxyphenylacetic acid (DOPAC), and to a lesser extent on deamination of methoxytyramine, the *O*-methylated metabolite of dopamine (Figure 29-4). As a result, HVA is formed in multiple tissues, with about 30% of circulating and urinary HVA arising from mesenteric organs and up to 20% from the brain.

With the exception of VMA, all the catecholamines and their metabolites are metabolized to sulfate conjugates by a specific sulfotransferase isoenzyme (SULT1A3). In humans, a single amino acid substitution confers the enzyme with particularly high affinity for dopamine and the *O*-methylated metabolites of catecholamines, including normetanephrine, metanephrine, and methoxytyramine.[48] The SULT1A3 isoenzyme is found in high concentrations in gastrointestinal tissues, which therefore represent a major source of sulfate conjugates.

In humans, VMA and the sulfates and glucuronide conjugates of MHPG represent the main end products of norepinephrine and epinephrine metabolism (Table 29-1). HVA and conjugates of HVA are the main metabolic end products of dopamine metabolism. These end products and the other conjugates are eliminated mainly by urinary excretion. As a result, their circulatory clearance is slow and plasma concentrations high relative to those of the precursor amines.

Serotonin is not a substrate for COMT and follows simpler pathways of metabolism than those for catecholamines (Figure 29-6). Deamination of serotonin to the aldehyde intermediate is preferentially followed by oxidation to 5-hydroxyindoleacetic acid (5-HIAA) catalyzed by

TABLE 29-1 Average Urinary Excretion of Catecholamines and Metabolites*

	Amount Excreted, μmol/day (μg/day)	Percent of Total from Norepinephrine and Epinephrine
Epinephrine (free)	0.03 (5)	0.1
Norepinephrine (free)	0.18 (30)	0.5
Epinephrine and norepinephrine (conjugated)	0.59 (100)	1.7
Metanephrine (free and conjugated)	0.33 (65)	1.0
Normetanephrine (free and conjugated)	0.55 (100)	1.6

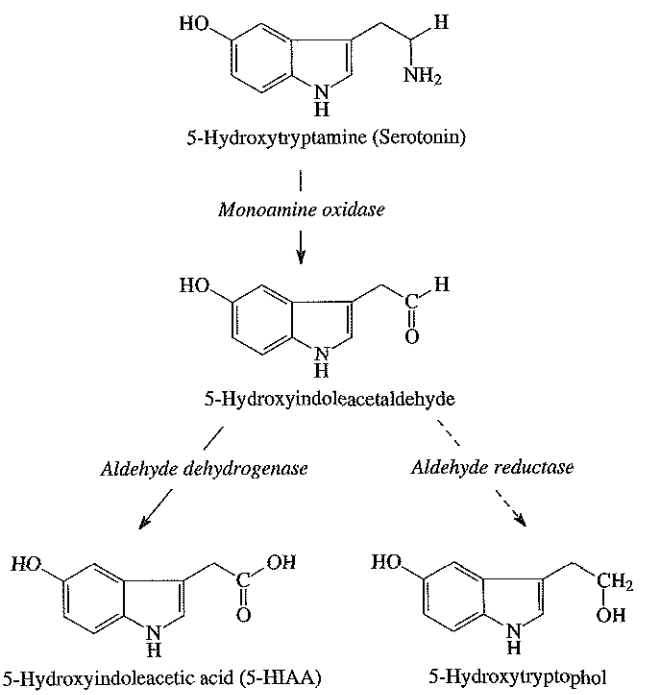

Figure 29-6 Metabolism of serotonin to 5-hydroxyindoleacetic acid (5-HIAA) and 5-hydroxytryptophol.

aldehyde dehydrogenase. Reduction to 5-hydroxytryptophol (5-HTOL) normally represents a relatively minor pathway, so that the major urinary excretion product of serotonin metabolism is 5-HIAA. Metabolism through these pathways is altered by consumption of ethyl alcohol, which through changes in the redox state leads to increased formation of 5-HTOL. Increases in ratios of 5-HTOL to 5HIAA in urine therefore provide a useful marker of alcohol abuse.

PHYSIOLOGY OF CATECHOLAMINE AND SEROTONIN SYSTEMS

The physiological and behavioral actions of catecholamines and serotonin provide a foundation for understanding disorders of monoamine excess or deficiency. Major sites of catecholamine and serotonin synthesis and action are listed in Table 29-2 for both central and peripheral nervous systems. The table provides an anatomic framework showing the location of adrenergic, dopaminergic, and serotonergic systems and the varying modes of signal transmission by the monoamines.

Catecholamines and serotonin regulate physiological events at the cellular level by interaction with families of cell-surface receptors. Adrenergic receptors, classified as α_1 (subtypes $\alpha_{1a,b,d}$), α_2 (subtypes $\alpha_{2a,b,c}$), β_1, β_2, and β_3 subcategories, initiate cellular events in response to epinephrine and norepinephrine.[35] Compared with norepinephrine, epinephrine demonstrates greater or equal affinity for α_1 and α_2 receptors, and equivalent potency with β_1 receptors. For β_2 receptor activation, epinephrine is tenfold to fiftyfold more potent than norepinephrine, and norepinephrine is tenfold more active toward β_3 receptors.[106] Dopamine has known pharmacological reactivity with α_1 and α_2 adrenergic receptors but transmits central and peripheral nerve signals primarily by selective interaction with a family of dopaminergic receptors designated as D_1, D_2, D_3, D_4, and D_5 subtypes.[82] An even larger family of serotonergic receptors subtypes ($5\text{-HT}_{1A,B,D,E,F}$, $5\text{-HT}_{2A\text{-}C}$, 5-HT_3, 5-HT_4, $5\text{-HT}_{5A\text{-}B}$, 5-HT_6, 5-HT_7) has been identified by histological and molecular

TABLE 29-2 Location of Monoamine Production and Action in the Body

	Site of Monoamine Production	Mode of Transmission	Tissue Location of Monoamine Action
Epinephrine	Adrenal medulla (chromaffin cells)	Hormonal	Cardiac muscle, smooth muscle, and widespread effects on cellular metabolism
Norepinephrine	Peripheral sympathetic ganglia and varicosities of autonomic nervous system	Neuroeffector cell junction	Effector tissue including cardiac muscle, smooth muscle, vascular endothelium, and exocrine glands
	Adrenal medulla (chromaffin cells)	Hormonal	Primarily cardiac and smooth muscle
	Brainstem (locus caeruleus and reticular formation)	Neuronal synapse	Widespread central nervous system (CNS) neuronal connections
Dopamine	Midbrain (substantia nigra)	Neuronal synapse	Neuronal connections in cerebral striatum
	Midbrain (ventral tegmentum)	Neuronal synapse	Cerebral mesolimbic and mesocortical neuronal connections
	Diencephalon (hypothalamus)	Neuronal synapse	Pituitary gland
	Retina	Neuronal synapse	Neuronal connections within the retina
	Olfactory bulb	Neuronal synapse	Neuronal connections within the olfactory bulb
	Gastrointestinal tract	Autocrine/paracrine	Regulation of bicarbonate secretion, gut motility, sodium handling, exocrine secretions
	Kidney (synthesized from circulating L-dopa)	Autocrine/paracrine	Regulation of natriuresis
Serotonin	Brainstem (raphe nucleus)	Neuronal synapse	Widespread CNS neuronal connections
	GI (enterochromaffin cells)	Hormonal (paracrine)	Gastrointestinal smooth muscle
	GI (enterochromaffin cells)	Platelet uptake/release	Platelets, vascular smooth muscle

techniques.[113] Receptors, including α_2-adrenergic, 5-HT_{1A}, 5-HT_{1B}, and 5-HT_{1D}, may serve as autoreceptors by turning off the release of their respective neurotransmitters via a negative feedback mechanism. The major physiological effects of catecholamines and serotonin, as outlined in the next section, are explained in part by these diverse receptor interactions that occur in function-specific locations throughout the vasculature and organ systems of the body.

Central Nervous System

Norepinephrine, dopamine, and serotonin represent only about 1% to 2% of the total neurotransmitters in the brain but serve an important role in autonomic (involuntary), somatic (voluntary), and information processing functions.[250] As neurotransmitters, they are produced primarily in regions of the brainstem (medulla oblongata, pons, and midbrain) by neurons with axons that project to defined, and sometimes widespread, areas of the brain or spinal cord. Although our understanding of central adrenergic, dopaminergic, and serotoninergic systems is incomplete, their role in central nervous system function and dysfunction is increasingly evident with important diagnostic and therapeutic implications.

Most norepinephrine synthesis in the brain takes place in the locus caeruleus of the pons and in the reticular formation of the medulla oblongata. About half of the norepinephrine is produced in the locus caeruleus by only a small nucleus of neurons that may respond in unison to sensory input signals.[188] The norepinephrine-producing neurons in the lower brainstem send diffuse axonal projections throughout the brain as high as the cerebral cortex. They also send descending fibers to the spinal cord where they synapse with preganglionic sympathetic neurons that communicate with the peripheral sympathetic nervous system. The norepinephrine-producing neurons of the brainstem process incoming sensory signals. They participate in regulating the activity of the sympathetic nervous system and the overall state of attention and vigilance. A predominant function of norepinephrine systems in the brain is response to stress. Stress-induced stimuli activate the brainstem production of norepinephrine with synaptic release and neuroactivation throughout many areas of the brain and spinal cord.

Dopamine is also an important neurotransmitter in the central nervous system. Dopamine accounts for more than half of the catecholamine production of the brain but its distribution and function are markedly different from norepinephrine. Dopamine neurotransmission is involved in processing sensory signals and in regulating hormonal release. Dopaminergic neurons in the retina and olfactory bulb have ultrashort projections that transmit signals within these neuronal centers for vision and smell. Neurons in the arcuate nucleus of the hypothalamus have projecting fibers that release dopamine in the portal vessels, exerting a key neuroendocrine inhibition on prolactin and thyroid-stimulating hormone release and as effects on other hormones of the pituitary gland.[201]

Dopamine is also produced by neurons in the substantia nigra and ventral tegmentum. The ventral tegmental area modulates diverse forebrain functions such as cognitive activity through axonal projection to the prefrontal cortex and reward seeking behavior via axonal fibers sent to limbic structures of the brain.[225] Consequently, disturbances in dopamine production and release from these areas of the brain are involved in a number of important neurological and psychiatric disorders, with dopamine receptors serving as key pharmacological targets for antipsychotic drug development.[227] In addition, dopaminergic neurons in the substantia nigra project into the corpus striatum to form an important nigrostriatal system, which regulates the initiation and maintenance of motor function. Control by this system over extrapyramidal (involuntary) movement is evidenced by the loss of motor control when nigrostriatal neurons degenerate in Parkinson's disease.[111]

Serotonin, like norepinephrine, is produced by small clusters of neurons in the brainstem regions but serves a diverse range of behavioral and physiological functions.[237] Neurons in the raphe nuclei of the pons and upper brainstem are a primary source of brain serotonin and project axonal fibers throughout the brain and spinal cord. Physiological and behavioral processes that may be influenced by this extensive serotonergic system include memory, learning, feeding behavior, sleep patterns, thermoregulation, pain modulation, cardiovascular function, and hypothalamic regulation of pituitary hormones. Each of the 14 known subtypes of serotonin receptors has distinct patterns of distribution in the brain and accounts for the diverse cognitive, behavioral, and physiological responses.[6] Raphe projections to the subcortical regions of the cerebral hemisphere (amygdala and hippocampus) activate receptors that influence mood and anxiety. The success in pharmacological manipulation of serotonin levels and selective receptor responses in the brain clearly indicates the importance of the central serotonergic system.[126] Buspirone, for example, reduces anxiety behavior by activation of serotonin autoreceptors in the subcortical areas of the brain, thus reducing serotonin release. Hypoactivity of the serotonergic system, on the other hand, plays an important role in depression. Selective serotonin reuptake inhibitors such as fluoxetine, paroxetine, and sertraline are effective agents in the treatment of this form of central serotonergic deficiency.[199]

Serotonin is also involved in hormonal regulation. Serotonin-releasing nerve fibers that originate in raphe nuclei and terminate in the hypothalamus exert a circadian influence on pituitary-adrenal function by stimulating hypothalamic corticotropin-releasing hormone and signaling other hormonal events mediated by enhanced prolactin and growth hormone release.[201] Serotonin also influences overall blood flow to the brain as evidenced by serotonin's vasoconstrictive effects on carotid vasculature and the beneficial pharmacological effect of a serotonergic agonist, sumatriptan, in the treatment of migraine.

Serotonin and catecholamine functions in the central nervous system are both diverse and complex, and direct assessment of central neurotransmitters by clinical laboratory methods is currently limited. The effects, however, of central serotonergic, dopaminergic, and serotonergic systems on metabolic and hormonal function are routinely measured in the clinical laboratory, and many of the therapeutic and illicit drugs that modulate central monoamine neurotransmission are monitored by laboratory techniques in a wide range of clinical settings.

Sympathetic Nervous System

In the peripheral nervous system, norepinephrine is an important neurotransmitter in the sympathetic branch of the autonomic system. Sympathetic nerve transmission operates below the level of consciousness in controlling physiological function of many organs and tissues of the body. The sympathetic system plays a particularly important role in regulating cardiovascular function in response to postural, exertional, thermal, and mental stress. With sympathetic activation, the heart rate is increased, peripheral arterioles are constricted, skeletal arterioles are dilated, and the blood pressure is elevated. In addition, sympathetic nerve stimulation dilates pupils; inhibits smooth muscles of the intestines, bronchi, and bladder; and closes the sphincters. Sympathetic signals work in balance with the parasympathetic portion of the autonomic nervous system to maintain a stable internal environment.

The hypothalamus, which integrates autonomic and neuroendocrine systems, has a controlling influence over sympathetic outflow from brainstem centers and the spinal cord. Afferent or incoming sensory signals originate from pressure, stretch, chemical, pain, and temperature receptors located in visceral organs and vessels. Afferent nerve impulses enter the central nervous system either to form the efferent component of local reflex arcs within the spinal cord or to ascend to higher centers such as the hypothalamus, where afferent signals are integrated with other neural pathways. Efferent or outgoing responses are transmitted by preganglionic sympathetic neurons that exit the spinal cord between the first thoracic and second lumbar segments. The exiting fibers converge on sympathetic ganglia chains along the spinal column or in visceral ganglia and activate multi-

ple postganglionic neurons by releasing the neurotransmitter acetylcholine. The terminal branches of the postganglionic fibers that project from these ganglia into target organs have varicosities that form a rich ground plexus for synaptic contact with a large number of effector cells in glands and muscle fibers.

Most sympathetic postganglionic nerves liberate norepinephrine as their neurotransmitter. In limited locations, sympathetic nerve endings release acetylcholine, such as some sweat glands that undergo a noradrenergic to cholinergic switch during development.[223] In addition, dopamine is an important neurotransmitter in renal, coronary, mesenteric, and cerebrovascular beds.[85] Preganglionic sympathetic fibers also innervate the adrenal medulla, stimulating release of epinephrine from chromaffin cells as a circulating hormone.

The relative contribution of individual organs to overall sympathetic activity has been inferred from data on the release of norepinephrine into plasma.[3,64,67] Plasma norepinephrine is derived primarily from postganglionic sympathetic neurons with little contribution from the central nervous system or hormonal release from the adrenal medulla. In the resting state, the overall rate of norepinephrine spillover to the systemic circulation is in the order of 200 to 600 ng/min. Because of intervening neuronal and extraneuronal removal processes, this spillover represents less than 10% of the total norepinephrine released by sympathetic nerves. Turnover of norepinephrine, representing a loss mainly caused by metabolism, is driven primarily in the resting state by leakage of norepinephrine from vesicles into the neuronal axoplasm. Major contributors to basal sympathetic outflow, based on spillover measurements, include the gastrointestinal (GI) tract (~37%), kidney (~25%), and skeletal muscle (~11%). The heart, liver, lungs, and skin each contribute less than 10%. Alterations in norepinephrine spillover occur in response to physiological and pathological states. Exercise, overeating, low salt intake, upright position, mental stress, and aging increase sympathetic outflow. Increased spillover is also found in disorders such as cardiac failure, hypertension, and depression. Reduction in baseline norepinephrine overflow from the heart has also been shown in autonomic insufficiency and syncope, consistent with sympathetic denervation or depressed sympathetic activity in these disorders.

The physiological response to sympathetic activity in individual organs is dependent not only upon the rate of neurotransmitter release from postganglionic nerve varicosities but also the type of adrenergic receptors and their location in tissue. Vascular and organ-specific responses are classified in Table 29-3 by subcategory of interaction with adrenergic receptors. In peripheral target organs, α_1 and β_1 adrenergic receptors appear strategically located in the immediate vicinity of nerve terminals for rapid postsynaptic smooth muscle, secretion, and endocrine activation via sympathetic signals from the brain. Postsynaptic β_2 adrenergic receptors in the heart also allow rapid sympathetic neuroactivation. Extrajunctional α_2 and β_2 receptors that are remote from sympathetic nerve terminals in vascular smooth muscle or platelets may be preferentially influenced by circulating catecholamines, such as epinephrine produced by the adrenal gland.[106]

An earlier concept of the sympathetic nervous system functioning primarily as an all-or-none responder to fight or flight has been challenged by studies indicating more specific organ responses to sympathetic activation.[122,182] Thermal and pain sensors, for example, result in a sympathetic response

TABLE 29-3 Direct Effects of Adrenergic Activation on Some Organ Systems Based on Receptor Subtype

Receptor Subtype (Relative Potency)	Tissue Location (Response)	
α_1-adrenergic (NE ≤ E)	Heart (increased force)	Arterioles (constriction)
	Veins (constriction)	Pupils (dilation)
	Adrenergic sweat glands (secretion)	GI sphincters (contraction)
	Urinary bladder sphincter (contraction)	Uterus in pregnancy (contraction)
	Spleen capsule (contraction)	Penis (ejaculation)
α_2-adrenergic (NE ≤ E)	Arterioles (constriction)	Adipocytes (inhibit lipolysis)
	GI motility and tone (decreased)	Intestinal secretions (inhibit)
	Pancreatic islet cell secretion (inhibit)	Platelet aggregation (stimulate)
β_1-adrenergic (NE = E)	Heart (increased rate and force)	Kidney (renin release)
	Adipocytes (stimulate lipolysis)	
β_2-adrenergic (NE << E)	Heart (increased rate and force)	Arterioles (dilation)
	Gallbladder and ducts (relaxation)	GI motility and tone (decreased)
	Adipocytes (stimulate lipolysis)	Bronchial muscle (dilation)
β_3-adrenergic (NE > E)	Adipocytes (stimulate lipolysis)	

Modified from references 106 and 147. The distribution of the six α_1 ($\alpha_{1a,b,d}$) and α_2 ($\alpha_{2a,b,c}$) subtypes is not completely understood and therefore not included in the table. For receptor locations in the central nervous system, refer to vonBohlen und Bohlen O, Dermietzel R. Neurotransmitters and neuromodulators. Handbook of receptors and biological effects. Darmstadt FRG, 2002.[250]

that differs markedly from the physiological response to the baroreceptor signals produced by changes in blood pressure. An increase in environmental temperature reduces sympathetic tone in peripheral vascular beds, thereby resulting in vasodilation and increased heat losses by radiation from the surface of the body. Pain receptor stimulation from surgical incision in anesthetized humans causes a proportionate increase in cutaneous vasoconstriction.[228] In a postural change from supine to upright, however, baroreceptors signal both cardiac and vascular responses via the sympathetic nerves. In the heart, sympathetic release of norepinephrine increases the rate and force of cardiac muscle contractions, ultimately increasing cardiac output. In skin and mucosa, sympathetic activation causes vasoconstriction with a resultant increase in blood pressure and redistribution of blood to visceral organs. Therefore although global sympathetic activation clearly operates in extreme conditions of stress, the differential control of sympathetic output is continually adapting cardiovascular and other organ functions in support of behavioral and environmental changes.

Adrenal Medullary System

Although often considered a part of the sympathetic nervous system, the adrenal medulla produces and secretes a different catecholamine, epinephrine, with different functions from the norepinephrine secreted by sympathetic nerves.[56] The adrenal medulla and sympathetic nerves are also regulated separately, often in divergent directions in response to different forms of stress.

The human adrenal glands overlie the superior poles of the kidneys. Each gland consists of an outer part, the lipid-rich cortex, and a thin inner central medulla containing chromaffin cells. The adrenal medulla is up to 2 mm thick and takes about one tenth of the entire weight of the gland. Blood is supplied to the adrenal medulla by direct arterial supply and from vessels draining from the cortex to the medulla. The latter supply provides an important source of adrenocortical steroids for regulation of adrenal medullary function. The neural input to the adrenal medulla includes direct innervation by cholinergic fibers that pass through the sympathetic paravertebral chain from preganglionic sympathetic cell bodies of the spinal cord.

A characteristic feature of adrenal medullary chromaffin cells is the presence of numerous catecholamine storage granules ranging in size from 100 to 300 nm in diameter. These granules turn brown when exposed to potassium bichromate solutions, ammoniacal silver nitrate, or osmium tetroxide because of the oxidation and polymerization of epinephrine and norepinephrine. This process is known as the "chromaffin reaction," hence the terms chromaffin cells and chromaffin granules. At least two kinds of adrenal medullary chromaffin cells have been identified in most animal species based on differences in chromaffin granules. Norepinephrine-producing chromaffin cells possess dense-core granules eccentrically located in the vesicle, and cells storing epinephrine have less electron-dense homogenous granules.

The human adrenal medulla produces mainly epinephrine, which as a hormone, is secreted directly into the bloodstream to act on cells distant from sites of release. As outlined previously, epinephrine and norepinephrine have overlapping but also different potencies of effect on α- and β-adrenergic receptors. The proximity of sites of norepinephrine and epinephrine release to adrenoceptors also determines differences in adrenoceptor-mediated responses to the two catecholamines. Because of these factors, epinephrine exerts its effects on different populations of adrenoceptors than norepinephrine. As a circulating hormone, epinephrine acts potently on β_2-adrenergic receptors of the skeletal muscle vasculature, causing vasodilation. In contrast, norepinephrine released locally within the vasculature causes α_1-adrenoceptor–mediated vasoconstriction. Increases in circulating epinephrine during stress may contribute to skeletal muscle vasodilatory responses, but appear to play little role in other cardiovascular changes, including increases in heart rate. Thus despite the potent hemodynamic actions of epinephrine, the adrenal medulla appears to play a minimal role in cardiovascular regulation compared with sympathetic nerves.

Epinephrine released from the adrenal glands is more important as a metabolic than as a hemodynamic regulatory hormone.[45] In particular, epinephrine stimulates lipolysis, ketogenesis, thermogenesis, and glycolysis and raises plasma glucose levels by stimulating glycogenolysis and gluconeogenesis. Epinephrine also has potent effects on pulmonary function, causing β_2-adrenoceptor–mediated dilation of airways. Circulating norepinephrine, in minor part derived from the adrenal medulla and functioning as a hormone, may have additional metabolic actions, but appears to have little importance for cardiovascular regulation compared with the higher concentrations of the amine at sympathoneuroeffector sites.

Despite the apparent importance of the adrenal medulla in homeostasis, particularly regulation of metabolism, the medulla in contrast to the adrenal cortex is not vital for survival. Studies in adrenalectomized subjects clearly show that both hemodynamic and glucose-counter-regulatory responses to insulin-hypoglycemia, exercise, and other manipulations remain intact despite absence of epinephrine responses.[46,105] This contrasts with the severe disturbances of blood pressure regulation accompanying loss of sympathetic nerves.

Compared with the sympathetic nervous system, the adrenal medulla makes a relatively minor contribution to the overall production and turnover of catecholamines (Table 29-4).

However, because phenylethanolamine-*N*-methyltransferase (PNMT) is expressed mainly in adrenal chromaffin cells, more than 90% of circulating epinephrine is derived from the adrenal medulla. This contrasts with

TABLE 29-4 Contribution of the Adrenals to Circulating Catecholamines and Metabolites

	Adrenals (pmol per min)	Total Body (pmol per min)	Adrenal Contribution (%)
Catecholamines			
Epinephrine	979	1075	91%
Norepinephrine	274	3953	7%
Dopamine	6	>290	<2%
Metabolites			
Metanephrine	449	494	91%
Normetanephrine	91	392	23%
DHPG	665	13,964	5%
DOPAC	300	>4120	<7%

circulating norepinephrine, more than 90% of which is derived from sympathetic nerves.

Apart from catecholamines, adrenal medullary chromaffin cells produce, store, and secrete a wide array of neuropeptides and proteins. Peptides include enkephalins, β-endorphin, neuropeptide Y, substance P, vasoactive intestinal peptide, neurotensin, galanin, atrial natriuretic peptide, pituitary adenylate cyclase-activating peptide, adrenomedullin, and corticotrophin. These peptides are secreted together with the catecholamines and may be involved in a local autocrine or paracrine regulation of adrenal medullary and cortical function. The major soluble proteins within chromaffin vesicles belong to the family of granins, which consist of several secretory acidic glycoproteins, the major representative being chromogranin A.

Peripheral Dopaminergic System

Dopamine is usually thought of as a neurotransmitter in the brain or as an intermediate in the production of norepinephrine and epinephrine in the periphery. It has been presumed that these sources account for the large amounts of dopamine and dopamine metabolites excreted in urine. The contribution of the brain to circulating levels and urinary excretion of dopamine metabolites is, however, now known to be relatively minor. Also, in sympathetic nerves and the adrenal medulla most dopamine is converted to norepinephrine. Therefore other sources and functions of dopamine in the periphery must be considered. Emerging evidence suggests the presence of a third peripheral catecholamine system, in which dopamine functions not as a neurotransmitter or circulating hormone, but as an autocrine or paracrine substance.[91]

In the kidneys, dopamine is now an established autocrine and/or paracrine effector substance contributing to the regulation of sodium excretion.[33] Unlike neuronal catecholamine systems, production of dopamine in the kidneys is largely independent of local synthesis of L-dopa by tyrosine hydroxylase. Thus renal denervation does not affect urinary dopamine excretion. Instead, production of dopamine in the kidneys depends mainly on proximal tubular cell uptake of L-dopa from the circulation. The L-dopa is then converted to dopamine by aromatic amino acid decarboxylase, the activity of which is up regulated by a high-salt diet and down regulated by a low-salt diet.

The presence of a renal dopamine paracrine-autocrine system explains the considerable amounts of free dopamine excreted in the urine.[258] Most derives from renal uptake and decarboxylation of circulating L-dopa and reflects the plasma levels of this amino acid and the function of the renal dopamine paracrine-autocrine system.

Although the kidneys represent the major source of urinary free dopamine, this source does not account for the larger amounts of excreted dopamine metabolites, such as HVA and dopamine sulfate. Findings of large arterial-to-portal venous increases in plasma concentrations of dopamine and its metabolites have indicated that substantial amounts of dopamine are produced and metabolized in the GI tract and other mesenteric organs.[55]

The substantial production and metabolism of dopamine in the human GI tract appear to reflect functions of dopamine as an enteric neuromodulator or paracrine and/or autocrine substance. Dopamine and dopamine receptor agonists stimulate bicarbonate secretion and protect against ulcer formation, whereas dopamine antagonists augment secretion of gastric acid and promote ulcer development.[76] Dopamine also appears to influence GI motility, sodium transport, and gastric and intestinal submucosal blood flow. In the pancreas, dopamine may modulate secretion of digestive enzymes and bicarbonate.

Morphological studies have demonstrated the presence of cells in the GI tract that contain dopamine and express components of dopamine signaling pathways, including catecholamine biosynthetic enzymes and specific dopamine receptors and transporters.[173] In the stomach, tyrosine hydroxylase is expressed in epithelial cells, including acid-secreting parietal cells. In the small intestine, cells of the lamina propria, including immune cells, also express tyro-

sine hydroxylase. The enzyme is additionally found in pancreatic exocrine cells.

The high rates of dopamine production by mesenteric organs cannot be accounted for by local extraction and decarboxylation of circulating L-dopa. Thus unlike the kidneys, where dopamine is produced mainly from circulating L-dopa, in the GI tract, production of dopamine requires the presence of tyrosine hydroxylase or other sources of L-dopa.

Consumption of food increases plasma concentrations of L-dopa, dopamine, and dopamine metabolites, particularly dopamine sulfate, indicating that dietary constituents may also represent an important source of peripheral dopamine.[94] Such a source does not, however, account for the substantial amounts of dopamine produced in peripheral tissue outside of the digestive tract, or of that produced in digestive tissue of fasting individuals. In particular, plasma concentrations of both L-dopa and dopamine sulfate remain high even after a 3-day fast. It is now clear that dopamine sulfate is mainly produced in the GI tract from both dietary and locally synthesized dopamine. This is consistent with findings that the GI tract contains high concentrations of the SULT1A3. Production of sulfate conjugates in the digestive tract appears to provide an enzymatic "gut-blood barrier," for detoxifying dietary biogenic amines and delimiting physiological effects of locally produced dopamine.

Enteric Nervous System

The enteric nervous system (ENS) is defined as an independent and integrated system of neurons and supporting cells located in the GI tract, gallbladder, and pancreas. It is the largest division of the autonomic nervous system and contains about the same number of neurons as the spinal cord. The ENS is composed of two networks or plexuses of intrinsic neurons, the myenteric plexus and the submucous plexus. Both are imbedded in the wall of the gut and extend from the esophagus to the anus. These networks contain more than 100 million sensory neurons, interneurons, and motor neurons. The myenteric plexus lies between the longitudinal and circular layers of intestinal smooth muscle and controls propulsive movements (peristalsis). The submucous plexus innervates glandular epithelium, intestinal endocrine cells, and submucosal blood vessels. This network senses the environment within the lumen, regulates local blood flow, and controls epithelial cell secretion.

The ENS is connected to the central nervous system by extrinsic parasympathetic and sympathetic motor neurons, and by extrinsic spinal and vagal sensory neurons. Through these bidirectional connections, the ENS can be monitored and modified.[5,96] Despite the presence of these extrinsic nerve connections, the ENS can also function autonomously in some intestinal regions. Neural transmission within the ENS is controlled by a large variety of neurotransmitters and neuromodulatory peptides, such as serotonin, norepinephrine, acetylcholine, ATP, and nitric oxide.[168] Most of these substances are also found in the brain. In addition to its function as a neurotransmitter within the ENS, serotonin also acts as a local paracrine molecule, participating in mucosal sensory transduction. More than 95% of the body's serotonin is located within the GI tract, with most being synthesized and stored in enterochromaffin cells in the gut mucosa. Serotonin is released from these cells in response to mechanical or chemical stimuli such as the passage of food, which in turn stimulates both intrinsic (via 5-HT_{1P} and 5-HT_4 receptors) and extrinsic (via 5-HT_3) vagal sensory nerve fibers.[80] Intrinsic sensory neurons activated by serotonin stimulate the peristaltic reflex and secretion, whereas extrinsic sensory neurons initiate bowel sensations such as nausea, vomiting, abdominal pain, and bloating. The paracrine actions of serotonin are terminated by uptake into epithelial cells by the same serotonin transporter used in serotonergic neurons.

Serotonin modulates numerous physiological and behavioral systems in the human body and is involved in a wide variety of clinical disorders. In the ENS, for example, serotonin plays pivotal roles in the pathogenesis of the carcinoid syndrome and the irritable bowel syndrome.[112] Differences in serotonin receptor subtypes provide a strong rationale for using pharmaceutical agents that selectively act on serotonin receptors in the treatment of these clinical disorders.[1]

CLINICAL APPLICATIONS

Catecholamines and serotonin have an important role in health and disease. For example, excess catecholamines are associated with stress, a fall in blood pressure or blood volume, thyroid hormone deficiency, congestive heart failure, and arrhythmias, and low levels of catecholamines are seen in idiopathic postural hypotension. Increased concentrations of circulating serotonin have been implicated in several pathological conditions, including chronic tension headache, hypertension, schizophrenia, Duchenne's muscular dystrophy, and preeclampsia. Although investigational measurement of catecholamines, serotonin, and their metabolites has been used in a range of pathophysiological processes, clinical laboratory measurement of the amines and their metabolites is primarily used in the diagnosis of neuroendocrine tumors. Catecholamine-secreting neurochromaffin tumors include pheochromocytomas, paragangliomas, and neuroblastomas; carcinoids are serotonin-secreting tumors. Measurement of catecholamines is also useful in the diagnosis of a number of autonomic and genetic disorders that will also be covered in this section.

Pheochromocytoma

Pheochromocytomas are catecholamine-producing tumors that arise from chromaffin cells of the adrenal medulla. Excluding neuroblastomas, about 10% of catecholamine-producing tumors arise from extraadrenal sympathochromaffin tissue, usually in the abdomen, and are known as

paragangliomas. Most other paragangliomas arise from parasympathetic tissue in the chest and neck and do not produce appreciable amounts of catecholamines.[169]

Pheochromocytomas and catecholamine-producing paragangliomas are treacherous tumors that will almost invariably cause devastating cardiovascular complications and death if not recognized and properly treated. Thus once such a tumor is suspected, it is imperative that appropriate biochemical tests are employed for accurate diagnosis.

The presence of a pheochromocytoma is usually suspected because of signs and symptoms that reflect the biological effects of catecholamines released by the tumor. Hypertension is the most common sign and can be sustained or paroxysmal. Symptoms include headache, palpitations, diaphoresis, pallor, dyspnea, nausea, attacks of anxiety, and generalized weakness. Although headache, palpitations, and sweating are nonspecific symptoms, their presence with hypertension should arouse immediate suspicion of the tumor. Signs and symptoms that occur in paroxysms reflect episodic catecholamine secretion. Paroxysmal attacks usually last less than an hour with intervals between attacks varying widely and as infrequent as once every few months. Pronounced but transient symptoms usually accompany such attacks, whereas symptoms are usually less pronounced when hypertension is sustained. For more detail on the clinical presentation and other aspects of pheochromocytoma, the reader is referred to the text of Manger and Gifford.[161] Pheochromocytomas are rare, occurring in less than 0.2% of patients with hypertension. However, because of the high prevalence of hypertension and the wide spectrum of symptoms produced by pheochromocytomas, many of which occur in other clinical conditions, pheochromocytomas must be considered in many patients with and without hypertension. Patients with a high risk for pheochromocytoma, in whom testing may be carried out independently of the presence of signs and symptoms, include those with a family or previous history of the tumor, or the finding of an adrenal incidentaloma.

Most pheochromocytomas are sporadic, but a significant proportion, perhaps as many as 25%, occur in several familial tumor syndromes.[190] Pheochromocytomas in multiple endocrine neoplasia type 2 (MEN 2a or 2b) result from mutations of the ret protooncogene. In MEN 2a, there is often coexistence of medullary thyroid cancer or C-cell hyperplasia and parathyroid adenoma or hyperplasia. In MEN 2b, hyperparathyroidism is rare, but patients often present with mucosal neuromas, thickened corneal nerves, and alimentary tract ganglioneuromatosis. In von Hippel-Lindau syndrome (VHL), family-specific mutations of the VHL tumor suppressor gene determine the varied clinical presentation of tumors, including retinal angiomas, central nervous system hemangioblastomas, pheochromocytomas, and tumors in the kidneys, pancreas, and testis. Familial paragangliomas (some catecholamine producing) occur secondary to mutations of genes for several succinate dehydrogenase enzymes. In addition to paragangliomas, these familial conditions also include a predisposition to adrenal pheochromocytomas. Neurofibromatosis type 1 is the most common familial condition coexisting with pheochromocytoma, which occurs in about 1% of patients with the condition. Periodic testing for pheochromocytomas in patients with the first 3 of the above 4 familial syndromes is now recommended as part of a routine screening and surveillance plan.

Although mostly benign, about 10% to 15% of pheochromocytomas are malignant. There is a higher risk of malignant pheochromocytomas in patients with large or extraadrenal primary tumors.[125] Diagnosis of a malignant pheochromocytoma is not possible based on histopathological features, but instead requires evidence of metastatic lesions (e.g., in liver, lungs, lymphatic nodes, and bones). Metastases can occur more than 20 years after removal of an apparently benign solitary tumor. Therefore all patients with a previous history of the tumor are at risk for recurrent or malignant disease and should undergo periodic screening for the tumor.

Adrenal masses are present in 6% or more of the older population. Most are benign adenomas, but up to 10% represent pheochromocytomas. With escalation in the use of computed tomography and magnetic resonance imaging, there has been an increasing frequency in incidental findings of adrenal masses during imaging procedures for unrelated conditions. These adrenal incidentalomas represent another situation in which biochemical testing for pheochromocytomas is now recommended, irrespective of the presence of the usual signs and symptoms of the tumor.[97]

Biochemical evidence of excessive catecholamine production is crucial for diagnosis of pheochromocytoma, and has traditionally relied on measurements of urinary catecholamines, metanephrines, and VMA.[218] Most patients with hypertension and symptoms caused by active pheochromocytomas have large increases in these analytes, making the tumor relatively easy to diagnose. Problems occur in those patients in whom hypertension is paroxysmal and where there may be negligible catecholamine secretion between episodes. False-negative test results are, however, more commonly encountered in patients with "silent pheochromocytomas" in whom testing is carried out, not because of signs or symptoms, but because of an adrenal incidentaloma or as part of a routine surveillance plan for recurrent or hereditary pheochromocytomas. In one study involving 35 patients with hereditary pheochromocytomas, rates of false-negative results for plasma and urinary catecholamines, urinary total metanephrines, and urinary VMA ranged from 29% to 53%; six patients (17%) had normal results for all four tests.[63]

Another problem common to biochemical tests used for diagnosis of a pheochromocytoma is that a positive result does not necessarily establish a tumor. False-positive results must always be expected when the upper reference limit for a test is set at anything less than the 100% confidence intervals of a reference population.

The above limitations in sensitivity and specificity of biochemical tests are compounded by the large numbers of patients commonly tested for pheochromocytomas, very few of whom have the tumor. The low pretest prevalence of pheochromocytomas means that false-positive biochemical results usually far outnumber true-positive results, making it difficult to unequivocally confirm the tumor in the vast majority of patients with positive results.

With issues of sensitivity and specificity in mind and consideration of the potential dangers and rarity of a pheochromocytoma, the most important consideration in choice of biochemical tests is their reliability for detecting and excluding the tumor. In a pheochromocytoma, a missed diagnosis caused by false-negative results can have catastrophic consequences for the patient. In contrast, false-positive results can be refuted by further tests. Therefore suitably sensitive biochemical tests remain the first choice in the initial workup of a patient suspected of harboring a pheochromocytoma.

Findings that none of the traditionally used biochemical tests could reliably detect all cases of pheochromocytomas led to recommendations that biochemical testing should include a combination of measurements of catecholamines and catecholamine metabolites. VMA is excreted in urine in large amounts, which makes measurement of this metabolite a simple, easy to implement, and time-honored test for diagnosis of pheochromocytomas. Numerous studies have now made it clear, however, that measurements of urinary VMA provide a relatively insensitive diagnostic test with limited value for initial testing for pheochromocytomas. Therefore the usual recommendation has been that biochemical testing should include measurements of urinary or plasma catecholamines and urinary metanephrines.

With the development of liquid chromatographic methods sensitive enough to measure the low levels of free metanephrines in plasma there has been increased emphasis on these measurements for diagnosis of pheochromocytomas.[155,213] Studies from three independent groups have now shown that measurements of plasma free metanephrines provide a superior method for diagnosis of pheochromocytomas than other commonly used tests of catecholamine excess.[157,211,221] In the largest of these studies,[157] involving biochemical testing in more than 1000 patients, including 214 with pheochromocytomas, measurements of plasma free metanephrines and urinary fractionated metanephrines provided the highest diagnostic sensitivities, but the plasma test provided higher diagnostic specificity than the urine test. Receiver-operating characteristic curves showed that a single test of plasma free metanephrines provided higher diagnostic efficacy than all other tests, even when carried out in combination. Based on these findings it was proposed that a single test of plasma free metanephrines is sufficient for initial testing, and prevents the increased chance of false-positive results associated with multiple tests. Measurements of plasma free metanephrines have also been recommended for all patients with adrenal incidentaloma.[97]

The basis for the high diagnostic efficacy of plasma free metanephrines is explained by several factors: (1) plasma free metanephrines are produced by metabolism of catecholamines within pheochromocytomas, a process that occurs continuously and independently of variations in catecholamine release by tumors[61]; (2) normally only small amounts of metanephrines are produced in the body, and these are relatively unresponsive to sympathoadrenal activation compared with the parent amines[57]; and (3) VMA and the metanephrines commonly measured in urine are different metabolites from the free metanephrines measured in plasma, and are produced in different parts of the body by metabolic processes not directly related to the tumor itself.[60]

Urinary metanephrines are usually measured after a deconjugation step and largely reflect levels of sulfate-conjugated metanephrines produced outside of tumor tissue. The sulfate conjugates of normetanephrine and metanephrine are present in plasma at twentyfold to thirtyfold higher concentrations than the free metanephrines, and are the main form eliminated in urine. Plasma and urinary concentrations of deconjugated metanephrines are therefore easier to measure than the free metanephrines. Provided that liquid chromatographic steps for fractionated measurement of normetanephrine and metanephrine are used, measurement of the deconjugated metabolites provide diagnostic sensitivity that approaches that of measurement of plasma free metanephrines. The main drawback appears to be lower diagnostic specificity. This is particularly problematic in patients with renal insufficiency, in whom plasma concentrations of the deconjugated metanephrines are strongly elevated.[181] In contrast, since the circulatory clearance of free metanephrines by extraneuronal uptake is a rapid process largely independent of renal function, false-positive test results for the free metabolites are less of a problem.

The high diagnostic sensitivity of measurements of plasma free or urinary fractionated normetanephrine and metanephrine makes these tests the most suitable choice for the initial work up of a patient with a suspected pheochromocytoma. Negative results by these tests virtually exclude a pheochromocytoma, whereas negative results by other tests do not. Exceptions include small or microscopic (<1 cm) tumors encountered during routine screening or tumors that do not synthesize norepinephrine and epinephrine.

Increases in plasma free or urinary fractionated metanephrines, such as normetanephrine and metanephrine, are usually high enough to conclusively establish the presence of most cases of pheochromocytomas. However, where increases are of smaller magnitude, false-positive results remain difficult to distinguish from true-positive results and additional biochemical testing is necessary. Ideally, such testing should conclusively establish the presence of a pheochromocytoma before imaging studies are undertaken and the patient is committed to surgery.

Before further biochemical testing is initiated, consideration should be given to eliminating possible causes of false-

positive results. These may occur because of inappropriate sampling conditions (e.g., blood sampling in nonfasting states or without a preceding 20 minute period of supine rest) or because of medications. The latter may involve direct analytical interference, such as co-chromatography of acetaminophen in high-performance liquid chromatography (HPLC) measurements of plasma normetanephrine. Usually, however, such sources of interference can be detected by careful inspection of chromatograms. More common causes of false-positive results are drugs that activate the sympathoadrenal system or influence the disposition of catecholamines. Tricyclic antidepressants and phenoxybenzamine (Dibenzyline) are particularly problematic, in one study accounting for 41% of all false-positive elevations of plasma normetanephrine and 44% to 45% of false-positive elevations of urinary and plasma norepinephrine.[59] Tricyclic antidepressants presumably increase levels of norepinephrine and normetanephrine by blocking reuptake of norepinephrine, thereby increasing the amounts available for *O*-methylation and that escape into the circulation. Phenoxybenzamine is a nonselective alpha-adrenergic blocking agent commonly used to treat patients with a pheochromocytoma. Presumably the drug elevates norepinephrine and normetanephrine by attenuating alpha$_2$-adrenoceptor–mediated feedback inhibition of norepinephrine release, possibly combined with reflexive sympathetic activation.

After the potential confounding influence of medications or other causes of false-positive results have been eliminated, some consideration should be given to the choice of additional biochemical tests and patterns of results necessary for more firmly establishing or refuting the diagnosis of a pheochromocytoma. When initial testing yields elevations in plasma normetanephrine, metanephrine, or both amines, this may be corroborated by a similar pattern of results after additional measurements of urinary normetanephrine and metanephrine. Conversely, when initial testing yields positive results for urinary fractionated metanephrines, additional measurements of plasma free metanephrines are useful.

Patterns of increases in plasma free metanephrines and catecholamines can also be useful for confirming pheochromocytomas in patients in whom initial tests of free metanephrines are positive but insufficiently elevated for a firm diagnosis.[59] More specifically, patients with a pheochromocytoma usually have larger relative increases in metanephrines than of the parent catecholamines, whereas patients with false-positive results caused by sympathoadrenal activation usually have larger increases in catecholamines than metanephrines.

The clinical presentation of the patient is also important to consider when interpreting patterns of biochemical results. Patients with tumors that produce large amounts of epinephrine (and also metanephrine) may present with hyperglycemia, dyspnea, and pulmonary edema, signs and symptoms reflecting the potent actions of epinephrine on glucose metabolism and pulmonary physiology. Such patients are also more likely to present with alternating hypotension and hypertension and to have symptoms that occur paroxysmally compared with patients with tumors that produce only norepinephrine (and hence also only normetanephrine). Pheochromocytomas associated with VHL disease produce exclusively norepinephrine and normetanephrine, whereas those occurring in patients with MEN 2 produce epinephrine and are best detected by increases in plasma free metanephrine, with or without accompanying increases in normetanephrine.[65]

Increases in plasma or urinary concentrations of L-dopa, dopamine, and methoxytyramine are not sensitive or specific markers of pheochromocytomas. However, when such increases accompany large increases in norepinephrine and normetanephrine, the pattern suggests metastatic disease. Pheochromocytomas that produce exclusively dopamine are extremely rare, but can be found in patients with paragangliomas, particularly where these have metastasized.

When biochemical testing continues to yield equivocal results, the clonidine suppression test may be useful for further confirming or excluding pheochromocytomas. As originally introduced by Bravo et al,[21] this test was designed to distinguish patients with increases in plasma catecholamines caused by pheochromocytomas from those with increases caused by sympathetic activation. By activating alpha$_2$-adrenoceptors in the brain and on sympathetic nerve endings, clonidine suppresses norepinephrine release by sympathetic nerves. Decreases in elevated plasma norepinephrine after clonidine therefore suggest sympathetic activation, whereas lack of decrease suggests a pheochromocytoma.

A problem with the clonidine suppression test is that patients with normal or mildly increased plasma levels of norepinephrine may have clonidine-induced decreases in plasma norepinephrine, despite the presence of a pheochromocytoma.[230,241] This is particularly troublesome since such patients represent those in whom it is most difficult to conclusively diagnose a pheochromocytoma. Additional measurements of plasma normetanephrine before and after clonidine have therefore been proposed to offer a useful method to overcome this limitation.[59] In a study involving 48 patients with and 49 patients without pheochromocytomas, lack of decrease and elevated plasma levels of norepinephrine or normetanephrine after clonidine confirmed pheochromocytomas with high specificity (98% to 100%). However, of 48 patients with pheochromocytomas, 16 had normal levels or decreases of norepinephrine after clonidine. In contrast, plasma normetanephrine remained elevated after clonidine in all but 2 patients, indicating higher sensitivity (96% versus 67%) and more reliable diagnosis using normetanephrine than norepinephrine responses to clonidine. Box 29-1 outlines the clonidine suppression test protocol with these added testing recommendations.

BOX 29-1 Protocol for Clonidine Suppression Test

Principle: Clonidine activates α_2-adrenergic receptors in the brain and sympathetic nerve endings to suppress norepinephrine release by sympathetic nerves without effect on catecholamine release from pheochromocytomas.

Indication: The test is used to discriminate patients with pheochromocytomas from patients with false-positive test results for catecholamines or metabolites in either plasma or urine.

Procedure: The test is best performed in the morning after an overnight fast. The patient remains recumbent throughout the entire procedure. A forearm venous cannula is placed for baseline and 3-hour blood sampling during the procedure. After at least 20 minutes of supine rest, a baseline blood sample is drawn in a heparinized tube. Clonidine, 4.3 µg/kg of body weight, is then given orally, and a repeat blood sample is drawn 3 hours later. The samples are analyzed for plasma catecholamines, with plasma normetanephrine measurement also recommended.

Interpretation: For optimum clinical specificity, a positive result highly suggestive of a pheochromocytoma includes an elevation of norepinephrine and normetanephrine at 3 hours and a failure to suppress norepinephrine more than 50% and normetanephrine more than 40 % below the baseline plasma level.

NEUROBLASTOMA

A neuroblastoma is a malignant neoplasm characterized in most cases by overproduction of catecholamines and their metabolites. It is a tumor of postganglionic sympathetic neurons and, like a pheochromocytoma, is of neural crest origin. Unlike pheochromocytomas, neuroblastomas rarely occur in adults[100] and are almost exclusively a pediatric cancer. Neuroblastomas account for approximately 7% of cancer in childhood and are the most common malignancy diagnosed in the first year of life.[98,99] The incidence of neuroblastomas is approximately 10 cases per million children, resulting worldwide in about 10,000 new cases per year.[166] Although familial cases have been reported,[148] the vast majority of neuroblastomas appear to develop sporadically.

The anatomic location of the primary tumor in neuroblastomas parallels the sympathetic nervous system, as predicted from its neuronal origin. The majority of tumors are intraabdominal, arising in the adrenal gland or the upper abdomen, and less frequent locations include the chest, neck, or pelvis regions. Approximately 60% of neuroblastomas are extra adrenal, compared with only about 10% of pheochromocytomas. Metastases in disseminated neuroblastomas may involve bone marrow, bone, lymph nodes, liver, and less frequently the skin, testis, and intracranial structures.

The biological behavior of a neuroblastoma ranges from regression and maturation to an aggressive course with an unfavorable outcome. Neuroblastomas are most notable for a subset of cases with complete regression or maturation to ganglioneuroma, a benign neoplasm. The high rate of neuroblastoma detection in infant screening programs compared with clinically diagnosed cases has also been explained by spontaneous tumor maturation.[110] The majority of clinically diagnosed tumors, however, are aggressive and have an unfavorable outcome.

The clinical stage of the disease (localized versus disseminated) is an important prognostic factor. Patients with early more localized stages of disease, or infants less than age 1 with a localized primary tumor and dissemination limited to skin, liver, and/or bone marrow, are considered to have a better prognosis than other stages.[23] Age at diagnosis is also important in predicting the course of the disease, with infants diagnosed with neuroblastomas in the first year of life having better survival rates.[42] Other factors, including expression of the N-*myc* (also known as *MYCN*) proto-oncogene and unfavorable histological classification, have been associated with an aggressive course of the disease. Unfortunately the overall incidence of metastatic neuroblastoma at the time of diagnosis is approximately 60%, and the need for earlier detection of children with the progressive disseminating tumors remains a diagnostic challenge.

Hypertension and other signs of sympathetic overactivity are uncommon in a neuroblastoma, in contrast with the sustained or paroxysmal hypertension associated with a pheochromocytoma. Patients commonly present with a tumor mass and clinical signs from compression effects on neighboring structures or hematological abnormalities from bone marrow involvement. The low incidence of hypertension and other signs of sympathetic overactivity may be attributed to the characteristic pattern of tumor storage and release of catecholamine and their metabolites. Catecholamine storage capacity in neuroblastoma cells is limited, as evidenced by electron microscopic findings of few secretory granules in comparison with pheochromocytoma cells.[118] Inefficient storage, coupled with excess production of catecholamines, may lead to an increase in the intracellular metabolism of the catecholamines and the release of mainly inactive metabolites. Hypertension, although rare, does occur in some patients with neuroblastomas, and an abundance of secretory granules has been noted in neuroblastoma tissue from some tumors.[176,254]

Laboratory evidence of a functional catecholamine-producing tumor is important in the clinical evaluation

when a neuroblastoma is suspected. The catecholamine and metabolite secretion patterns, however, may differ markedly among patients with the tumor. Neuroblastoma cells have the capacity to synthesize dopamine and norepinephrine, depending upon their degree of metabolic maturity, but like postganglionic sympathetic neurons, lack phenylethanolamine *N*-methyltransferase and do not produce epinephrine. Because of variability in catecholamine production and metabolism in neuroblastomas there is no single reliable marker of catecholamine overproduction, and a combination of catecholamine and/or metabolites is often measured in the diagnostic evaluation.

VMA and HVA are the most widely used determinations in both the clinical setting and in screening programs for diagnosis of a neuroblastoma. Elevated urinary excretion of HVA and VMA is the result of excess tumor production of dopamine and norepinephrine, respectively. A small diurnal variation in HVA and VMA excretion and a positive correlation between random and 24-hour urine test results allow the convenient use of random urine specimens, with results expressed as the ratio of catecholamine metabolites to creatinine excretion. Clinical sensitivity in the range of 90% has been reported for urinary HVA and VMA testing by some centers.[152,245] Others have, however, reported a lower rate of neuroblastoma detection. In a large neuroblastoma screening program, in which the population with negative screening results was tracked for occurrence of neuroblastomas, an elevation in VMA, HVA, or both acid metabolites detected only 73% of the tumors.[222] Patients with early stage disease have the highest rate of false-negative test results,[207] and screening programs have been generally unsuccessful in reducing the rate of metastatic neuroblastoma in the population.[110]

Additional markers of catecholamine overproduction have been employed to improve the biochemical detection of neuroblastomas. Free dopamine may be abnormal in urine from neuroblastoma patients with VMA and HVA excretion.[29,196,214] Combined testing for VMA, HVA, and dopamine may therefore improve tumor detection, and in 1993 an international consensus report on neuroblastoma diagnosis added dopamine to the list of acceptable measurements to document the adrenergic nature of the tumor.[23] Plasma measurements of dopamine and L-dopa, the amino acid precursor of dopamine, may also have clinical value and allow the alternate use of plasma.[66,93,102] Measurement of methylated metabolites, especially normetanephrine, has also been explored.[29] When urinary normetanephrine, metanephrine, methoxytyramine, dopamine, norepinephrine, VMA, and HVA were measured, clinical sensitivity for detection of neuroblastomas was 97% to 100% when results of normetanephrine testing were coupled either with VMA in the infants or with HVA in children greater than age 1.[180] Even with an extended panel of catecholamines and metabolite measurements, a low incidence of nonsecreting tumors continues to be identified and should be considered in the interpretation of a negative test result.

The pattern of catecholamine metabolism is associated with important biological and genetic prognostic factors in neuroblastomas. Lower excretion rates of VMA, HVA, dopamine, and norepinephrine are found more often in infants with early stages of the disease, which may explain the lower clinical sensitivity of VMA and HVA testing reported in patients with an early stage neuroblastoma. Elevated levels of catecholamines and their metabolites in urine, on the other hand, are related to aggressive behavior.[264] The prognostic value of VMA and HVA levels, however, has been studied; when disease stage and age at diagnosis are taken into account, the level of VMA and HVA did not have any additional prognostic significance.[42]

The relative excretion of catecholamines and their metabolites may also point to an unfavorable outcome in neuroblastomas. Immature metabolic patterns have been observed in neuroblastoma tumor tissue, based on excretion of dopamine or HVA relative to norepinephrine or VMA. A high ratio of HVA/VMA, dopamine/VMA, or dopamine/norepinephrine indicates a relative deficiency in beta hydroxylation with a reduction in tumor cell conversion of dopamine to norepinephrine. The immature metabolic pattern has been associated with aggressive tumor behavior and other unfavorable prognostic factors,[119,152,264] but the clinical application of metabolic patterns has not been established.

Finally, clinical specificity in detecting neuroblastomas with catecholamine and metabolite measurements may be influenced by the choice of laboratory methods, dietary interference, and other catecholamine-overproduction conditions. Significant advances in the analytical specificity of laboratory methods have reduced much of the exogenous interference, and histopathology remains the ultimate diagnostic criterion for distinguishing neuroblastomas from pheochromocytomas or other catecholamine-producing neurogenic tumors, such as ganglioneuromas and ganglioneuroblastomas.

Dysautonomias and Genetic Disorders

Dysautonomias are conditions in which altered function of the autonomic nervous system adversely affects health.[92] Such conditions range from more common transient episodes in otherwise healthy people (e.g., neurocardiogenic syncope), to progressive neurodegenerative diseases (e.g., multiple system atrophy), and to even more rare genetic disorders, such as dopamine β-hydroxylase deficiency (Table 29-5).

Dysautonomias also range from mechanistically straightforward disorders in which altered autonomic function plays a primary pathophysiological role (e.g., pure autonomic failure), to conditions in which altered autonomic function worsens an independent pathophysiological state (e.g., cardiac failure), and to more mysterious disorders in which the involvement of the autonomic nervous system is less clear (e.g., chronic fatigue syndrome). Abnormalities of blood pressure control represent the common presenting clinical features of the dysautonomias. In those involving

TABLE 29-5 Dysautonomias Featuring Altered Sympathetic Nervous Function, Disorders of Adrenal Medullary Function, and Genetic Disorders of Catecholamine Systems

Inhibition/ Interruption		Activation
Dysautonomias		
Neurocardiogenic syncope	*Common*	Obesity
Diabetic autonomic neuropathy		Essential hypertension
Parkinson's disease		Congestive heart failure
Hyperthyroidism		Postural tachycardia syndrome
Multiple system atrophy		Intracranial bleeding
Quadriplegia		Renovascular hypertension
Amyloidosis		Hypothyroidism
Pure autonomic failure		Baroreflex failure
Familial dysautonomia		Guillain-Barré syndrome
Dopamine β-hydroxylase deficiency		NE transporter deficiency
	Rare	
Adrenal medullary dysfunction		
Obesity	*Common*	Neurocardiogenic syncope
Diabetes		Panic disorder
Addison's disease		Pheochromocytoma
Congenital adrenal hyperplasia		Adrenal medullary hyperplasia
	Rare	

Genetic disorders (not included above): tyrosine hydroxylase deficiency; dopa-responsive dystonia; dihydropteridine reductase deficiency; aromatic L-amino acid decarboxylase deficiency; Menkes' disease; monoamine oxidase deficiency.

inhibition or interruption of sympathetic outflow, the presenting clinical feature is usually hypotension, particularly orthostatic hypotension. In those involving sympathetic activation, there is often hypertension—and in some, excessive increases in heart rate upon standing.

In most dysautonomias, altered or deranged sympathetic nervous function is evident from measurements of plasma or urinary levels of norepinephrine or norepinephrine metabolites. The most well-known dysautonomias, in which measurements of norepinephrine provide useful and even crucial information for diagnosis, involve the autonomic failure syndromes, particularly pure autonomic failure and multiple system atrophy.[167] The most important debilitating clinical manifestation in both conditions is orthostatic hypotension. In their most severe forms, patients are unable to remain in the upright posture for even a few minutes. The basis of the disorder involves failure of neurogenic vasoconstrictor responses secondary to defective sympathoneural release of norepinephrine. In pure autonomic failure, the lesion is postganglionic, involving degeneration of sympathetic nerves and lack of norepinephrine release, whereas in multiple system atrophy, the lesion is preganglionic and sympathetic nerves are present but do not release norepinephrine appropriately. The two syndromes can therefore be diagnosed based on measurements of catecholamines. In both there are usually absent or significantly attenuated increases in plasma concentrations of norepinephrine in response to assumption of upright posture. In pure autonomic failure, levels of norepinephrine and its metabolites are usually severely decreased, reflecting loss of sympathetic nerves. In contrast, in multiple system atrophy resting levels of catecholamines and catecholamine metabolites may be normal or even increased.

In addition to altered sympathetic function in dysautonomias, there are also clinical conditions involving dysfunction of the adrenal medulla (Table 29-5). According to a view promulgated by Canon,[35] the sympathetic and adrenal medullary systems function as a single emergency system. It has now, however, become increasingly clear that sympathetic and adrenal medullary systems are regulated separately and often in divergent directions.[56] This is illustrated by the relatively common clinical conditions of obesity and neurocardiogenic syncope. Sympathetic nervous activation in obesity is implicated to contribute to obesity-related hypertension, whereas decreased epinephrine release may participate in the changes in fatty acid metabolism and energy metabolism that accompany and contribute to weight gain. In neurocardiogenic syncope, β-adrenoceptor–mediated vasodilation—resulting from increased circulating epinephrine—combined with reduced α-adrenoceptor–mediated vasoconstriction, caused by withdrawal of sympathetic tone, are both implicated in contributing to orthostatic hypotension.

With the exception of pure autonomic failure and pheochromocytomas, abnormalities in plasma or urinary levels of catecholamines in most of the above disorders, particularly those that are more common, are usually subtle and not easily interpreted. Plasma or urinary levels of catecholamines and catecholamine metabolites in such conditions have mainly been measured for purposes of research, to better characterize and understand the particular disorder. Resulting improved understanding of such disorders, combined with advances in measurement techniques and improved ability to interpret different patterns of neurochemical results, will likely lead to increasing use of measurements of catecholamines and catecholamine metabolites for routine diagnostic and prognostic purposes. This is becoming particularly apparent for the conditions that have a hereditary basis or are due to de novo mutations of specific genes, in which advances in molecular genetics are enabling precise identification of the genetic abnormality.[90]

Familial dysautonomia, dopamine β-hydroxylase deficiency, norepinephrine transporter deficiency, and congenital adrenal hyperplasia include dysautonomias or conditions associated with adrenal medullary dysfunction in which the specific genetic abnormalities have been identified. There are also other disorders involving mutations of genes coding for proteins involved in catecholamine synthesis and metabolism in which the clinical manifestations do not clearly involve the sympathoadrenal systems or may be so globally severe that abnormalities of autonomic or adrenal medullary function are obscured (Table 29-5).

Deficiencies of tyrosine hydroxylase or of enzymes involved in production of tetrahydrobiopterin cofactor (e.g., dopa-responsive dystonia) usually result in presentation of severe neurological abnormalities in early childhood. Depending on the exact mutation, deficiencies of tyrosine hydroxylase can involve moderate to severe loss of enzyme activity, most accurately diagnosed by low cerebrospinal fluid levels of catecholamine metabolites, such as MHPG and HVA, but normal levels of 5-HIAA.[19,20] In the autosomal dominant form of dopa-responsive dystonia (Segawa disease), failure to synthesize tetrahydrobiopterin cofactor leads to a similar clinical and neurochemical phenotype as in the rarer tyrosine hydroxylase deficiency syndrome.[226] In contrast to classical forms of tetrahydrobiopterin deficiency, characterized by phenylketonuria (e.g., dihydropteridine reductase deficiencies), deficiencies of guanosine triphosphate (GTP) cyclohydrolase responsible for dopa-responsive dystonia are not accompanied by hyperphenylalaninemia and require diagnosis by measurements of pterins and pterin metabolism, in addition to measurements of catecholamine metabolites.[14]

Patients with aromatic L-amino acid decarboxylase deficiency present with clinical and biochemical manifestations that overlap those of the tyrosine hydroxylase deficiency states described previously. However, this deficiency state is characterized by additional decreases in CSF and urinary levels of 5-HIAA.[114] Also, levels of L-dopa in urine, plasma, and cerebrospinal fluid are increased, and not decreased as in the other deficiency states. Levels of 5-hydroxytryptophan are similarly increased.

The major clinical feature of patients with deficiency of dopamine β-hydroxylase is orthostatic hypotension caused by reduced synthesis and release of norepinephrine by sympathetic nerves.[9] The deficiency is characterized neurochemically by decreased levels of norepinephrine and norepinephrine metabolites and increased levels of dopamine and dopamine metabolites. Diagnosis is best achieved from an increased ratio of plasma dopamine to norepinephrine. Copper deficiency in Menkes' disease is due to defects in the gene coding for a copper-transporting adenosine triphosphatase.[129] Because dopamine β-hydroxylase is a copper-dependent enzyme, the deficiency is associated with decreased activity of the enzyme and reduced production of norepinephrine from dopamine. Prompt diagnosis at childbirth is essential for copper-replacement therapy, and is best achieved from measurements of ratios of plasma concentrations of DOPAC or L-dopa to DHPG.

Congenital adrenal hyperplasia is a relatively common genetic disorder that occurs secondary to deficiencies of certain enzymes, usually 21-hydroxylase, responsible for synthesis of cortisol.[172] The disorder is characterized clinically by adrenal insufficiency with or without salt wasting, virilization, and in girls genital ambiguity resulting from increased androgen levels. As a result of the importance of adrenocortical steroids for adrenal medullary function and for maintaining activity of phenylethanolamine *N*-methyltransferase, the disorder is also characterized by adrenal medullary hypofunction and decreased epinephrine release and intraadrenal metabolism to metanephrine. Decreased plasma levels of metanephrine provide a biomarker of disease severity that may be useful for prognosis and directing therapy.[38]

Isolated deficiencies of MAO A and B are extremely rare and are associated with distinct clinical and neurochemical phenotypes.[154] Deficiency of MAO A is associated with a behavioral disorder characterized by increased aggressiveness. Plasma and urinary levels of deaminated metabolites of catecholamines are severely decreased, whereas levels of normetanephrine and metanephrine are increased. An increased ratio of plasma normetanephrine to DHPG has therefore been proposed to provide a sensitive marker for the deficiency state. In contrast, deficiency of MAO B is associated with a mild phenotype, the only biochemical alteration is increased urinary excretion of phenylethylamine.

Carcinoid

Carcinoids are the most common tumors arising from the diffuse neuroendocrine system of the GI tract and pancreas. Derived primarily from enterochromaffin cells, these tumors are widely distributed in the body but found with greatest frequency in the GI tract (74%) and respiratory tract (25%). Carcinoids are often classified as APUDomas (*a*mine *p*recursor *u*ptake and *d*ecarboxylation) because of the ability of enterochromaffin cells to take up and decarboxylate amino acid precursors of biogenic amines. In this regard, carcinoid tumors share certain pathological and biological similarities with pheochromocytomas.

The usual carcinoid tumor is solid and yellow-tan in appearance. Tumor cells exhibit a monotonous morphology, with pink granular cytoplasm and round nuclei with infrequent mitoses. Most carcinoids can be recognized by their reactions to silver stains and to neuroendocrine cell markers, such as chromogranin and neuron-specific enolase. Ultrastructurally, carcinoids possess numerous membrane-bound, electron-dense neurosecretory granules. These granules contain peptide hormones and bioactive amines, which can occasionally be identified by immunocytochemical techniques.

Carcinoid tumors are traditionally classified according to their presumed origin from the embryonic foregut

(bronchus, lung, stomach, duodenum, and pancreas), midgut (ileum, jejunum, appendix, and proximal colon), or hindgut (rectum and distal colon).[146] The most common sites for these tumors are the bronchus and/or lung (33%), ileum and/or jejunum (20%), rectum (10%), and appendix (8%).[177] A new classification system has also been proposed that takes into account variations in histopathological characteristics.[31] The overall incidence of clinically significant carcinoids in the United States has been estimated to be 1 to 2 cases per 100,000 persons. Carcinoid tumors may develop in all age groups, but they appear most frequently in adults, with a mean age of 63 for tumors of the small intestine and respiratory tract.[124] Clinically, most patients are asymptomatic until metastases are present. Bowel obstruction and abdominal pain are the most frequent presenting symptoms.

Carcinoid tumors show aggressive malignant behavior depending on the origin, depth of penetration, and size of the primary tumor.[123] Most rectal carcinomas are found incidentally at endoscopy. They are often less than 1 cm and have a low rate of metastasis, even though they may show extensive local spread. Carcinoids of the appendix are seen in about 1 in every 300 appendectomies. Almost all are less than 1 cm, and distant metastasis is rare. By contrast, 90% of intestinal carcinoids that penetrate halfway through the muscle wall will have spread to lymph nodes and distant sites at the time of diagnosis. More than 70% of intestinal carcinoids 1 to 2 cm in diameter metastasize to the liver. Fortunately, most carcinoid tumors grow slowly, and patients may live for many years. The 5-year survival rate of patients with carcinoids of the appendix is about 99%. Patients with carcinoids in the small intestine have a 5-year survival rate of about 50%.

As with normal gut endocrine cells, carcinoids synthesize, store, and release a variety of hormones and biogenic amines. One of the best characterized of these substances is serotonin. Carcinoid tumors also produce and secrete other biologically active substances, including histamine, kallikrein, bradykinins, tachykinins, prostaglandins, dopamine, and norepinephrine. Production of these substances varies in relation to the tissue origin of the tumor.[192] For example, midgut carcinoids release large quantities of serotonin into the circulation, whereas tumors derived from the foregut secrete primarily 5-hydroxytryptophan (5-HTP) (a serotonin precursor) and histamine rather than serotonin.[135] Primary hindgut carcinoids usually show no secretory activity. In some instances, carcinoid tumors may coexist with other endocrine tumors that produce gastrin, insulin, adrenocorticotropic hormone (ACTH), and catecholamines. Gastric foregut carcinoids may be associated with MEN 1.[32]

Secretion of vasoactive substances into the systemic circulation plays an important role in the development of the carcinoid syndrome. The full-blown syndrome associated with the humoral manifestations of these tumors is striking but uncommon, usually occurring only after metastasis to the liver and release of these substances directly into the systemic circulation. The classic clinical presentation of the carcinoid syndrome includes pronounced flushing (especially on the face and neck), diarrhea, bronchoconstriction, and eventual right-sided valvular heart failure. Overproduction of serotonin is found in 90% to 100% of patients with the carcinoid syndrome and is thought to be responsible for the diarrhea by its known effects on gut motility and fluid secretion. Serotonin receptor antagonists relieve the diarrhea in most cases. The pathophysiology of carcinoid flushing is not yet known, but tachykinins, bradykinins, and histamine may be mediators. Somatostatin analogues reduce circulating levels of these vasodilators. The causative agents of bronchoconstriction are also unknown, but tachykinins and bradykinins are likely mediators.

The clinical chemical evaluation of the carcinoid syndrome relies on measurements of serotonin and its metabolites in body fluids and tissue.[133] In patients with the typical carcinoid syndrome, 5-HTP is converted to serotonin and stored in tumor secretory granules and in platelets. A small amount of serotonin remains in plasma, but most is converted to 5-HIAA, which is excreted in urine. These patients have increased blood and platelet serotonin levels and increased urinary 5-HIAA. However, some foregut carcinoid tumors lack the aromatic L-amino acid decarboxylase and secrete 5-HTP rather than serotonin into the bloodstream.[193] Patients with these tumors have normal serotonin concentrations in blood and in platelets, but urinary levels are increased because 5-HTP is converted to serotonin in the kidney; urinary 5-HIAA levels may be slightly elevated.

Patients with serotonin-producing carcinoid tumors usually have striking increases in urinary 5-HIAA excretion (at least tenfold), but occasionally elevations are smaller. False-positive elevations can occur if the patient ingests serotonin-rich foods or medications, such as bananas, pineapples, chocolate, walnuts, pecans, kiwi fruit, plums, avocados, and cough medicines containing guaifenesin.[72,138] Conversely, alcohol, aspirin, and other drugs can suppress 5-HIAA levels. Patients should avoid these agents during 24-hour urine collections. Incomplete or excess 24-hour urine collections may be more accurately assessed in terms of a creatinine ratio. Fasting plasma 5-HIAA has been proposed as a convenient replacement for urine collections.[52]

The upper limit of the normal reference interval for urinary 5-HIAA excretion is variably defined and may be as low as 6 mg/day (30 μmol/day) if dietary and medicinal intake are controlled, or as high as 15 mg/day (80 μmol/day) to reduce false-positive results.[191] At an intermediate value of 10.7 mg/day (56 μmol/day), urinary 5-HIAA has a reported 77% sensitivity and 97% specificity for carcinoid disease.[34] To exclude the presence of a carcinoid tumor, lower cutoff values may be preferred (higher sensitivity); to confirm the presence of a carcinoid tumor, higher cutoff values (higher specificity) would be indicated.

Most physicians rely on the measurement of 5-HIAA to diagnose carcinoid syndrome. But when a patient strongly suspected for carcinoid syndrome shows normal or borderline increases in urinary 5-HIAA, documentation of elevated serotonin levels in platelets, plasma, whole blood, or urine may help establish the diagnosis.[134] Platelet serotonin has been reported to be more sensitive than urinary 5-HIAA for detecting carcinoids that produce small or moderate amounts of serotonin, such as foregut and hindgut carcinoids and midgut carcinoids with a low tumor volume.[171] Also, platelet serotonin levels are not affected by the patient's diet. Platelets can be saturated at high serotonin secretion rates, however, and 5-HIAA is often preferred for monitoring high serotonin production.

Attempts are being made to identify more sensitive and specific markers for carcinoids. For example, measurement of chromogranin A in serum is reported to be more sensitive than urinary 5-HIAA in detecting carcinoid tumors and may reflect tumor size, but specificity is lower.[193] Plasma levels of neuron-specific enolase, neuropeptide K, and substance P have also been suggested as diagnostic and prognostic markers in carcinoid tumors.

ANALYTICAL METHODOLOGY

Numerous methods have been proposed for the determination of catecholamines, serotonin, and their metabolites in biological fluids. In clinical practice, laboratory determinations are performed primarily for diagnosis and follow-up of patients with catecholamine- or serotonin-secreting tumors. Most laboratories measure urinary free catecholamines, metanephrine, normetanephrine, and VMA in the evaluation of pheochromocytomas, and plasma catecholamine measurements are used in some medical centers and plasma metanephrines have been applied more recently. For detection of neuroblastomas, urinary HVA and VMA are most commonly ordered in clinical practice, but other catecholamine metabolites and dopamine are also measured. Diagnostic evaluation of patients with carcinoid tumor routinely involves the measurement of 5-HIAA, and the measurement of serotonin in platelets and urine has been advocated. In this section, we focus on current clinical laboratory methods with attention to sample preparation, current analytical techniques, and reference intervals. Protocols for selected methods used in current practice are available on this book's accompanying Evolve site, found at http://evolve.elsevier.com/Tietz/textbook.[216] Earlier fluorometric, spectrophotometric, and radioenzymatic methods are briefly addressed, with more extensive coverage in an earlier work by Rosano and co-workers.[218]

Catecholamines and Metabolites

HPLC, coupled with electrochemical or fluorometric detection, now provides the most widely used assay method for measurements of urinary or plasma catecholamines in the routine clinical laboratory.[58,183,218] Once equipment is purchased and trained staff are in place, the technique can provide reliable, reproducible, and relatively rapid measurements of large numbers of samples at minimum cost per sample. Problems with interference from drugs or dietary constituents are relatively easy to identify by careful inspection of chromatograms. Consistent sources of interference are usually remedied by simple changes to chromatographic conditions. A large number of different HPLC methodologies have been described, each requiring a preanalytical extraction step to concentrate (plasma) and cleanup (plasma and urine) the sample.

In contrast to the catecholamines, measurements of urinary metanephrines and VMA are still based in some routine laboratories on the early spectrophotometric assays developed by Pisano, Crout, and others in the late 1950s and early 1960s.[204,205] Despite subsequent development of a variety of preanalytical cleanup and extraction procedures, these assays remain susceptible to analytical interference. They are also restricted to measurements in urine. Another limitation for spectrophotometric or fluorometric assays of urinary metanephrines is that these methods do not allow separate (fractionated) measurements of normetanephrine and metanephrine.

Tests of urinary total metanephrines, as measured by spectrophotometric assays, are best abandoned in favor of measurement methods that incorporate a chromatographic step to fractionate normetanephrine and metanephrine and allow their separate measurement. Since significant numbers of pheochromocytomas produce mainly or solely only one of the two metabolites, separate measurements help to ensure that small or mild increases in one metabolite are not diluted by the normal levels of the other. Additionally the chromatographic step provides an additional level of selectivity, thereby minimizing analytical interference. Although HPLC with electrochemical detection provides the most widely available measurement method for urinary fractionated metanephrines, newer methods involving mass spectrometry are likely to offer further improvement. These methods, including gas chromatography–mass spectrometry and liquid chromatography–tandem mass spectrometry,[36,44,242] should provide higher analytical specificity than HPLC methods, which with continuing improvements in instrumentation and cost should become more widely applicable for diagnostic purposes.

Collection and Storage of Samples

The conditions under which plasma or urine samples are collected can be crucial to the reliability and interpretation of test results. Many clinicians prefer 24-hour collections of urine over blood sampling since the former avoids many of the rigid sampling conditions associated with blood collections and is more convenient for clinical staff to implement. However, 24-hour collections of urine are not always easily, conveniently, or reliably collected by patients, particularly pediatric patients. Also, influences of diet and sympathoadrenal activation associated with physical activity or

changes in posture are not as easily controlled for as they are for blood collections.

Because of the possible errors resulting from incomplete 24-hour urine collections or uncontrolled influences of physical activity, some investigators advocate spot or overnight urine collections.[104,131,202] Correction for differences in duration of collection is achieved by normalizing catecholamine or catecholamine metabolite excretion against urinary creatinine excretion. Additional considerations for urine collected under these conditions include dietary protein, muscle mass, level of physical activity, and time of day, all of which impact creatinine excretion and may further confound interpretation of results.[27,47,189,252]

Studies on the stability of catecholamines in urine and plasma have yielded mixed results with variable recommendations on appropriate preservatives and methods of collection.* Elaborate techniques for sample preservation as recommended in earlier years now appear to be largely unnecessary. Variable findings may be explained by autooxidation, particularly at alkaline pH, or deconjugation, particularly at low pH—two processes with opposing effects on levels of free amines. The general recommendation is that catecholamines in urine samples are best preserved with hydrochloric acid (HCl) to maintain urine acid. Aliquots are best stored frozen over protracted periods of time at –80 °C to further minimize autooxidation and deconjugation. Similarly, blood samples are best collected into tubes containing heparin or ethylenediaminetetraacetic acid (EDTA) as an anticoagulant and stored on ice before centrifugation at 4 °C, with separation of plasma for further storage at –80 °C.

Interferences from and Influences of Diet and Drugs

Dietary constituents or drugs can either cause direct analytical interference in assays or influence the physiological processes that determine plasma and urinary levels of catecholamines and catecholamine metabolites. In the former circumstances, the interference can be highly variable depending on the particular measurement method. In the latter circumstances, interference is usually of a more general nature and independent of the measurement method (Table 29-6).

Development of new drugs, variations in assay techniques, and continuing improvements in analytical procedures often make it difficult to identify which directly interfering medications should be avoided for a given analytical test. More readily identifiable and generalized sources of interference that are independent of the particular assay method tend to be associated with drugs that have primary actions on catecholamine systems. Because of the importance of these systems as therapeutic targets, such drugs represent a relatively common source of false-positive results.

Tricyclic antidepressants in particular are a major source of false-positive results for measurements of norepinephrine and normetanephrine in plasma or urine.[59] Presumably this is due to the primary inhibitory actions of these agents on monoamine reuptake. The result is an increased escape of norepinephrine from sympathetic nerve terminals into the bloodstream.[68,248]

Other medications that can cause significant interference but that are less commonly encountered during testing for pheochromocytomas include L-dopa, Sinemet, alpha-methyldopa (Aldomet), and MAO inhibitors. L-dopa that is used alone or as carbidopa (Sinemet) for the treatment of Parkinson's disease is an alumina-extractable catechol and the direct precursor of dopamine. The drug can therefore interfere directly with catecholamine assays and is also converted by catecholamine synthesizing and metabolizing enzymes to catecholamine products and metabolites with additional interfering actions.[40,210] Similarly the antihypertensive agent alpha-methyldopa is metabolized by catecholamine biosynthetic and metabolizing enzymes to alpha-methyldopamine, alpha-methylnorepinephrine, and other products, which in some but not all assays can result in significant interference.[49,184] Because active cellular uptake and not metabolism is the main determinant of catecholamine clearance, inhibitors of MAO have little effect on plasma or urinary catecholamines.[54] However, by blocking the main pathway for catabolism of the *O*-methylated catecholamine metabolites, MAO inhibitors can cause substantial increases in plasma levels and urinary excretion of normetanephrine and metanephrine.[62,251]

Reference Intervals

Interpretation of a biochemical test result as normal or abnormal depends on availability of valid reference intervals (see Chapter 16). For tests of a single analyte, such as VMA, it can be expected that at least 2.5% of patients without pheochromocytomas will have values for the analyte above the upper reference limit and 2.5% below the lower reference limit. Up to a 5% incidence of false-positive results might be expected for tests of pairs of analytes, such as norepinephrine and epinephrine in tests of urinary or plasma catecholamines or normetanephrine and metanephrine in tests of plasma free or urinary fractionated metanephrines. False-positive rates usually, however, tend to be higher than expected; this is likely due to reduced control over sampling conditions and sources of interference or differences in clinical characteristics of reference and patient populations.

Use of appropriately matched reference populations can be important for effective diagnosis of monoamine-producing tumors among different populations of patients tested for such tumors. Urinary and plasma levels of catecholamines and metanephrines show different ranges in hypertensives or hospitalized patients compared with normotensive healthy volunteers,[142,183,219] children compared with adults,[183,214,256] and males compared with females.[57,79] Also, levels of catecholamines and metanephrines in 24-hour urine specimens and plasma are not normally distributed.[156,219] Normalization of distributions, usually achiev-

*References 16, 18, 175, 203, 220, 255.

able by logarithmic transformation, is therefore useful for establishment of valid reference intervals.

Patients with hypertension tend to have higher plasma and 24-hour urinary levels of catecholamines and metanephrines than normotensives.[57,89,142,153] Use of reference intervals established in hypertensive rather than normotensive populations therefore minimizes the likelihood of false-positive results in patients tested for pheochromocytomas because of signs and symptoms. However, these same reference intervals are not necessarily appropriate for patients with pheochromocytomas who are normotensive and asymptomatic and tested for the tumor because of a hereditary predisposition or a finding of an adrenal incidentaloma. In some of these patients, the tumor may be too small to produce large enough amounts of catecholamines or catecholamine metabolites for a positive test result using reference intervals established in hypertensive or hospital patient populations. For these patient populations, use of reference intervals established in normotensive healthy volunteers may be more appropriate.

Reference intervals for plasma and urinary catecholamines and catecholamine metabolites also differ according to sex and age. Females have lower plasma concentrations of epinephrine and metanephrine than males.[57] Similarly, 24-hour urinary outputs of catecholamines and metanephrines are lower in women than men[79,128]; for epinephrine this difference remains significant when values are normalized for creatinine excretion.[79] Plasma levels of norepinephrine and normetanephrine increase with advancing age in adults, whereas plasma levels of epinephrine and metanephrine are little affected.[57] Age-related increases in 24-hour urinary outputs of norepinephrine and normetanephrine have also been reported,[128,153] but not consistently by all studies.[79] In general, the influences of age

and sex on adult reference intervals are minor and perhaps only relevant to consider for patients with borderline normal or abnormal biochemical test results.

Of greater importance than the age- and sex-related differences in adults are the much larger differences in plasma concentrations and urinary outputs of catecholamines and their metabolites in children compared with adults. Because of the dynamic changes that occur throughout childhood, and also because of the difficulty of obtaining complete urine collections, a standard practice for biochemical testing in children is to normalize excretion of catecholamines and metanephrines to that of creatinine. When this is done, ratios of urinary catecholamines or metanephrines to creatinine show a decrease with age through childhood.[30,163,214] It is therefore imperative that age-appropriate reference intervals be used for biochemical testing in children.

Another patient population in which the usual reference intervals are often invalid and in which diagnosis of a catecholamine-producing tumor can prove particularly difficult involves patients with renal failure.[18,238] In end-stage renal failure, urine collections may be impossible, and even in less severely affected patients results of 24-hour urine testing are difficult to interpret.[179] Impaired renal function results in dramatic increases in plasma concentrations of VMA and sulfate-conjugated metanephrines, rendering these tests invalid.[164,181] In contrast, since the circulatory clearance of plasma catecholamines and free metanephrines is largely independent of renal function, measurements of these analytes in plasma represent the most appropriate tests for diagnosis of pheochromocytomas in renal failure.[84] Nevertheless, plasma levels of catecholamines and free metanephrines tend to be elevated more in patients with renal failure than in normal and hypertensive populations. Also, dietary and medication-associated interferences with chromatographic analysis tend to be much more pronounced in patients with renal failure, making it difficult to obtain reliable results.

Plasma Catecholamines

Highly sensitive, specific, and reliable assay methods are required for measuring the normally very low concentrations of epinephrine, norepinephrine, and dopamine in plasma. Both unconjugated (free) and sulfoconjugated catecholamines circulate in human plasma and are increased in plasma from patients with pheochromocytomas.[209] Clinical measurement of the active free form is preferred because of the potential influence of diet on the conjugated fraction.

The earliest chemical assays were fluorometric methods, but radioenzymatic, radioimmunoassay (RIA), enzyme immunoassay (EIA), HPLC, and gas-liquid chromatography (GLC) methods with flame ionization, electron capture, or mass spectrometric detection have also been reported. Currently, HPLC assays are commonly employed for the determination of epinephrine and norepinephrine in plasma.[17,108,143] However, HPLC methods do require preliminary extraction and concentration of plasma to measure the very low levels of catecholamines found in normal subjects. The most common pretreatment involves alumina extraction, with or without a cation-exchange step; boric acid gels provide an alternate approach for selective adsorption of catecholamines. Organic solvents, acid deproteinization, ultrafiltration, and other solid phase extraction procedures can also be used to pretreat samples.[107,212] Many HPLC procedures analyze the plasma extract using reversed-phase chromatography with ion-pairing reagents; others use cation-exchange HPLC columns to separate the extracted amines. Electrochemical detection using amperometric or coulometric measurement is commonly used to quantify the catecholamines; detection limits are similar to those of radioenzymatic methods. HPLC separation can also be coupled to fluorescence detection, but precolumn or post-column derivatization techniques are required to enhance sensitivity and specificity. Automated procedures have been described that are sensitive, precise, and suitable for routine clinical applications; manual pretreatment may or may not be required.[53,130,262]

A method for measuring plasma free catecholamines based on HPLC with amperometric detection is available on this book's accompanying Evolve site and representative adult reference intervals[243] for plasma catecholamines are shown in Table 29-7.

Plasma Metanephrines

The metanephrines, normetanephrine and metanephrine, and the *O*-methylated metabolite of dopamine, methoxytyramine, are present in plasma in free and sulfate or glucuronide conjugated forms. Plasma concentrations of the conjugates are twentyfold to thirtyfold higher than those of the free metabolites. Rather than reflecting differences in rates of formation, the higher plasma levels of conjugated

TABLE 29-7 Plasma Catecholamine Reference Intervals for Adults

Position	Norepinephrine pg/mL (pmol/L)	Epinephrine pg/mL (pmol/L)	Dopamine pg/mL (pmol/L)

metabolites reflect their relatively slow circulatory clearance by renal extraction and elimination in the urine.[88] This contrasts with the free metabolites, which are cleared rapidly from the bloodstream by active extraneuronal uptake mechanisms throughout tissue of the body.

The free *O*-methylated amine metabolites are present in plasma at picomolar concentrations that have made their accurate measurement technically difficult. Measurements of plasma metanephrines therefore represent relatively recent developments. The first method enabling accurate measurement of plasma free normetanephrine involved a radioenzymatic assay in which normetanephrine was converted to ^{3}H-labeled metanephrine using preparations of the enzyme phenylethanolamine-*N*-methyltransferase, incubated with ^{3}H-methyl-labeled *S*-adenosylmethionine.[141] This method, however, did not allow measurements of metanephrine or methoxytyramine, and therefore had limited clinical utility.

The first HPLC methods for measuring plasma metanephrines in the early 1990s featured an acid-hydrolysis step similar to that used for routine measurements of urinary metanephrines.[181] These measurements of plasma deconjugated (free plus conjugated) metanephrines indicated promise for diagnosis of pheochromocytomas. Very high levels of the deconjugated metabolites were also found in patients with renal failure.

An HPLC method for the more difficult measurement of plasma free metanephrines was first described in 1993.[155] This method, like those involving measurements of plasma or urinary deconjugated metanephrines, requires a preanalytical cation-exchange extraction and purification step. The low plasma concentrations of free metanephrines present several technical challenges. In particular, low levels of interfering substances, such as acetaminophen, tend to be more troublesome to measurements of plasma concentrations of the free metabolites than to the higher deconjugated metabolites. Consequently, there is a necessity for a more rigorous preanalytical extraction and purification procedure than required for the deconjugated metabolites. The requirement for high analytical sensitivity also requires a specialized electrochemical detection system and relatively pulse-free solvent delivery system. Optimal separation of the *O*-methylated amines from potentially interfering substances is best achieved using relatively long chromatographic run times of up to 40 minutes, a limiting factor for sample throughput.

Despite the above difficulties and limitations, the original HPLC method for measurement of plasma free metanephrines has been reproduced and improved upon in numerous clinical laboratories. Improvements include a method that is free from interference from the commonly used pain medication acetaminophen.[213] Such developments have been driven by increasing recognition of the high diagnostic sensitivity of measurements of plasma free metanephrines for detection of pheochromocytomas. There remains a continuing necessity for further improvements in assay technology that will increase robustness of the method and more widely advance portability of the method to the routine clinical chemistry laboratory. This need is being met by commercial development of HPLC kit methods and technical advances in measurement methods. Liquid chromatography coupled with tandem mass spectrometry represents one such advance offering considerable promise for analytically specific, high-throughput measurements suitable for the routine clinical chemistry laboratory.[216] Improvements in detection sensitivity have already extended application of this method from measurements of urinary deconjugated metanephrines[242] to the much lower levels of free metanephrines in plasma. Representative reference intervals for plasma concentrations of free and deconjugated (free plus conjugated) metanephrines in normotensive and hypertensive adults and in normotensive children are shown in Table 29-8.

Plasma L-dopa, DOPAC, and DHPG

HPLC measurements of plasma catechols are usually limited to dopamine, norepinephrine, and epinephrine. However, with an alumina adsorption extraction procedure it is also possible to simultaneously measure several other catechols by HPLC[58] or microchip electrophoresis.[240] These catechols include DHPG, the deaminated metabolite of norepinephrine and epinephrine; DOPAC, the deaminated metabolite of dopamine; and 3,4-dihydroxyphenylalanine (L-dopa), the immediate precursor of dopamine. All are present in plasma at concentrations many fold higher than the catecholamines, making their detection relatively simple once appropriate chromatographic separation is achieved.

Each of the above catechols can provide unique and useful clinical information about the function of peripheral catecholamine systems.[87] DHPG in plasma is almost exclusively derived from deamination of norepinephrine in sympathetic nerves. These measurements therefore provide information about the activity of MAO. Decreases in plasma DHPG combined with reciprocal increases in normetanephrine, as assessed by plasma DHPG/normetanephrine ratios, provide a particularly useful method for identifying patients with deficiencies of MAO. DHPG is derived in part from deamination of the norepinephrine recaptured by sympathetic nerves and in part from leakage of the transmitter from storage vesicles into the sympathetic axoplasm. Provided appropriate procedures are employed to distinguish the two sources, measurements of DHPG can therefore be used to evaluate norepinephrine transporter function and assess the state of sympathoneural transmitter stores.

Since DHPG is derived almost exclusively from sympathetic nerves, it has also been proposed that these measurements might be useful for distinguishing patients with high plasma norepinephrine concentrations caused by sympathetic activation from those with high norepinephrine concentrations caused by a pheochromocytoma.[24] Unfortunately, because some pheochromocytomas produce significant quantities of DHPG,[233] use of plasma norepinephrine/DHPG ratios has turned out to have limited value for diagnosis of pheochromocytomas.

Approximately 8% of the L-dopa synthesized in sympathetic nerves is not converted to dopamine, but instead escapes into the bloodstream. Plasma concentrations of L-dopa therefore provide information about the activity of tyrosine hydroxylase, the rate-limiting enzyme in catecholamine synthesis.[95] Changes in plasma L-dopa also occur in a variety of disorders that feature derangements in catecholamine synthesis. Patients with neuroblastomas can have extremely high plasma L-dopa levels.[66,93] Elevated plasma L-dopa concentrations occasionally also occur in patients with pheochromocytomas, particularly patients with malignant disease.[93] Small amounts of circulating L-dopa also appear to be derived from melanocytes, where the amino acid is produced during phase I melanogenesis. Thus highly elevated plasma L-dopa levels can occur in patients with melanoma, particularly where this is associated with development of metastases.[69,158] Increases in plasma L-dopa also occur in patients with deficiencies of aromatic L-amino acid decarboxylase, and decreases occur in inherited disorders featuring impaired tyrosine hydroxylase activity.

Although simultaneous measurements of plasma L-dopa, DHPG, and the catecholamines offer considerable clinical utility, adoption of the method in the routine clinical chemistry laboratory is limited by several technical problems. First, separation of all the catechols and of DHPG from the solvent front requires relatively low mobile phase concentrations of organic modifiers. This consequently leads to long chromatographic run times that limit high throughput of more of the commonly requested catecholamines. Second, interference from uric acid presents a problem to measurement of DHPG by most amperometric detectors. This problem can be overcome using a coulometric electrode system for irreversible oxidation of uric acid with detection of catechols at a reducing instead of the more commonly used oxidizing potential. Third, recoveries of DHPG, L-dopa, and DOPAC from alumina tend to be lower than for the catecholamines, presenting some problem to their accurate measurement. This latter problem can be resolved by use of minimum quantities of alumina, close attention to types and strengths of acids used in the elution of catechols from the alumina, and additional correction for differences in recoveries from the internal standard.[109]

Alternatives to simultaneous measurements of the various plasma catechols include methods for individual measurements more suitable for specific applications. Examples include HPLC measurements of L-dopa and 3-*O*-methyldopa in Parkinson's disease or malignant melanoma.[8,13,158]

Representative reference intervals for plasma concentrations of L-dopa, DOPAC, and DHPG in normotensive adults are shown in Table 29-9.

Urinary Free Catecholamines

Urinary catecholamines represent a quantitatively small but diagnostically important component of the catecholamine excretion products. Catecholamines are excreted in the urine as free amines and as glucuronide and sulfate conjugates. As with plasma measurements, total urinary catecholamines (conjugated and unconjugated forms) may be measured by

hydrolyzing the sample before assay, but free amines are routinely measured because they are least affected by dietary catechols.[178]

Earlier fluorometric methods for analysis of urinary free catecholamines have been replaced by HPLC methods that allow selective quantitation of epinephrine, norepinephrine, and dopamine. Preliminary extraction of urine is still required and numerous preanalytical cleanup techniques are available. An alumina extraction procedure is typically coupled with ion-exchange or adsorption chromatography. Alumina pretreatment usually involves a batch extraction technique in which catechols are first adsorbed at pH 8.6 and then eluted with boric acid, which forms a complex with *cis*-diol groups. Purification on boric acid affinity gels provides an alternative procedure for selective adsorption of catecholamines.

Electrochemical detection with ion-pairing adaptations of reversed-phase chromatography is the most common methodology, and ion pairing with alkyl sulfonates or sulfates is generally used to enhance retention of cationic amine moieties on lipophilic stationary phases.[58,183,218] Potential analytical interference, depending upon chromatographic conditions, has been reported with α-methyldopa,[183] acetaminophen,[257] labetalol,[71] and captopril.[43] By varying the sample preparation procedures, metanephrines and VMA[77,200] may be co-analyzed along with the catecholamines. Alternate use of ion-exchange chromatography coupled with electrochemical detection offers separatory and sensitivity advantages, especially in detecting small tumors that preferentially secrete epinephrine.[11,170,259] More recently, tandem mass spectrometry methodology has been developed with high throughput capability and the added specificity resulting from tandem mass spectral detection.[149]

Representative reference intervals for unconjugated catecholamines, based on 24-hour outputs[183] and creatinine excretion,[214] in normotensive children and adults are shown in Table 29-10. Diagnostic testing based on overnight rather than on 24-hour urine collection has been suggested as a sensitive diagnostic index of autonomous catecholamine secretion by a pheochromocytoma.[124] However, reference intervals must be established for these studies because excretion of catecholamines varies during the sleep-wake cycle.[218]

Urinary Fractionated Metanephrines

Normetanephrine and metanephrine are metabolic products of norepinephrine and epinephrine, respectively, and are formed by the action of catechol-*O*-methyltransferase without deamination. As a result of active neuronal reuptake and deamination of norepinephrine, normetanephrine normally represents <5% of the total norepinephrine excretion products in urine. Metanephrine, however, even with its lower urinary concentration relative to normetanephrine, represents a major excretion product of epinephrine.[144] The metanephrines are excreted in both conjugated and unconjugated forms.[26] Unlike the catecholamines, total metanephrine excretion is not significantly influenced by diet.[178] As a result, the total metanephrines are routinely measured after acid hydrolysis or sulfatase pretreatment.

Selective quantitation of metanephrine and normetanephrine by HPLC techniques[7,197,229] is preferred and should be used in place of earlier spectrophotometric methods. Isolation of metanephrines from the urine is usually accomplished with ion-exchange chromatography. Weak cation-exchange resins are primarily used, although some procedures use a combination of strong and weak cation exchange to enhance recovery. Differential solvent extraction methods (e.g., using ethyl acetate and cyclohexane) can also be applied to remove potential interference. Although native fluorescence and ultraviolet absorption can

TABLE 29-11 Urinary Metanephrine and Normetanephrine Reference Intervals

be used to detect the metanephrine concentrations, most HPLC procedures are based on electrochemical detection. Column conditions and stationary phases vary; typical applications include reversed-phase chromatography with ion-pairing reagents and silica-based cation-exchange chromatography. Drug interference, which may falsely increase the HPLC-based estimation of normetanephrine, has been reported for viloxazine[10] and acetaminophen.[257] Labetalol and buspirone (BuSpar) may also interfere with metanephrine analysis,[71] and treatment with α-methyldopa results in additional chromatographic peaks.[41,59,120] A fractionated metanephrine method, performed by HPLC coupled with tandem mass spectrometry, offers the advantages of short chromatographic run time, high sample throughput, and elimination of drug interference.[242]

Table 29-11 shows representative reference intervals for metanephrine and normetanephrine in children and adults.[243] One-hour excretion of metanephrines has also been used in the detection of pheochromocytomas but diurnal variation in metanephrine excretion[232,239] must be considered when short collection intervals are used.

Urinary Vanillylmandelic Acid

Vanillylmandelic Acid (VMA) is a major catecholamine metabolite formed by the actions of catechol-*O*-methyltransferase and MAO. It is excreted by the kidney and represents an average of 40% to 50% of the urinary excretion production of norepinephrine and epinephrine. Norepinephrine is the major source of VMA, with metabolism through MHPG as the major pathway.[25,144] VMA is not significantly conjugated and therefore is measured without a hydrolysis step. VMA was first isolated and identified in the urine of a patient with a pheochromocytoma,[13] and its analysis is commonly performed to detect the presence of pheochromocytomas and neuroblastomas.

Earlier spectrophotometric methods for determination of VMA are relatively nonspecific and have been replaced by gas chromatography or more commonly by HPLC methods. Gas chromatographic methods with flame ionization or mass spectrometric detection that have been applied to the determination of VMA are highly specific and can simultaneously determine VMA and HVA.[22,70,244] HPLC is, however, the most frequently used chromatographic method, featuring isocratic reversed-phase separation with electrochemical, spectrophotometric, fluorometric, or postcolumn detection.[73,78,215] Anion-exchange chromatography has been used effectively to isolate VMA from urine before HPLC analysis.[12] HPLC applications are relatively free of interference and may provide simultaneous measurement of VMA and other metabolites.[37,199,234] A liquid chromatography–tandem mass spectrometry method for determination of VMA has been developed and introduced into clinical laboratory practice.[159]

Representative reference intervals for VMA excretion in normotensive children and adults,[206] based on both 24-hour urine and creatinine output, are listed in Table 29-12.

Urinary Homovanillic Acid

Homovanillic acid (HVA) is the principal urinary metabolite of L-dopa and dopamine. It has particular relevance to the diagnosis and management of neuroblastomas. HVA can be assayed using several spectrophotometric and chromatographic methods. Most of the earlier photometric procedures were based on the nonspecific reaction of nitrosonaphthol with biogenic amines. However, many compounds interfere with these assays, and earlier spectrophotometric methods have been replaced by chromatographic methods, such as gas chromatography,[22] gas chromatography–mass spectrometry,[70] and HPLC. HPLC methods are the most popular and most applications employ reversed-phase column chromatography and detection of the HVA peak by ultraviolet, fluorescence spectrometry,[4,83] or amperometry[12,15,28,234] techniques. HPLC methods with electrochemical detection are sensitive, show little interference from endogenous or exogenous organic acids, and may provide simultaneous measurement of VMA and other metabolites.

TABLE 29-12 Urinary VMA Reference Intervals

Serotonin and Metabolites

Serotonin

A variety of analytical methods have been used for the determination of serotonin in body fluids and tissue.[133] The oldest assays involved the extraction of serotonin from interfering compounds and quantitation by spectrofluorometric procedures using the native fluorescence of serotonin ($\lambda ex = 300$ nm, $\lambda em = 340$ nm at neutral pH). Derivatization with Ninhydrin or *o*-phthalaldehyde increased the sensitivity and selectivity of these fluorometric methods. More specific and precise methods have subsequently been introduced, including radioenzymatic assay, RIA, EIA, gas chromatography, and HPLC. Reagent and/or test kits based on some of these techniques are available commercially.

HPLC with either fluorometric[2,34,150] or electrochemical[139,140] detection is the most frequently used chromatographic method. HPLC techniques have been developed for measuring serotonin separately or adapted for simultaneous measurement of metabolically related indoles, such as 5-HTP and 5-HIAA. Preliminary extraction and deproteinization are required before analysis, and several choices are available. Organic solvent extraction was one of the first methods used to isolate serotonin, but solvent partition has been largely replaced by procedures that employ cation-exchange resins. Other solid phase extraction procedures have also been employed, such as reversed-phase chromatography using disposable cartridges of ODS-silica. A number of methods simply deproteinize with perchloric acid or trichloroacetic acid before injecting the sample directly onto the HPLC column.

Most HPLC assays employ octadecylsilyl (C18) reversed-phase columns, although strong cation-exchange columns have also been used. The chromatography is usually performed with an isocratic mobile phase at an acid pH that contains an organic modifier and perhaps an ion-pair reagent.[160] Serotonin is protonated in the pH range of 3 to 6, and addition of an anionic ion-pair reagent creates an uncharged conjugate, which enhances the affinity of serotonin for the hydrophobic stationary phase. For measurements of very small amounts of serotonin or for specialized projects, HPLC with amperometric or coulometric detection is often favored over fluorometric detection. Serotonin is readily oxidized electrochemically, and the current that flows is proportional to concentration. For serotonin, the oxidation potential is below 0.6 V, which reduces the risk of electrochemical interference by other compounds. If other tryptophan metabolites are analyzed simultaneously, however, higher oxidation potentials are required. The lower limit of detection, defined as the lowest injected amount that produces a signal-to-noise ratio of 3, is typically 20 nmol/L for whole blood serotonin and 1 nmol/L for platelet-free plasma serotonin.[208] Interassay reproducibility, expressed as a coefficient of variation, is about 6% at a serotonin level of 1140 nmol/L.

To enhance analytical sensitivity, some HPLC procedures incorporate precolumn derivatization with fluorescent[127] and chemiluminescent[117] reagents, thereby achieving detection limits in the femtomole range. Completely automated analyses of serotonin have been described, and some systems incorporate direct injection and online solid phase extraction.[136] For laboratories that may not have the equipment, staff, or experience to measure serotonin by HPLC, alternative technologies based on RIA and EIA are available as commercial test kits. These procedures are highly sensitive and

TABLE 29-14 Serotonin Reference Intervals

Biological Sample	Mass Units	Conversion Factor	Molar Units	Reference
Whole blood	50-200 ng/mL	×5.68	280-1140 nmol/L	243
	88-1230 ng/10^9 platelets	×0.00568	0.5-7.0 nmol/10^9 platelets	34
Serum	30-200 ng/mL	×5.68	170-1140 nmol/L	116
Urine	60-167 µg/day	×5.68	340-950 nmol/24 hr	137
	38-101 µg/g creatinine	×0.653	25-66 µmol/mol creatinine	134
CSF	1.0-2.1 ng/mL	×5.68	5.7-12.0 nmol/L	133
Platelet-rich plasma	670 ± 150 ng/10^9 platelets	×0.00568	3.81 ± 0.87 nmol/10^9 platelets	138
Isolated platelets	620 ± 233 ng/10^9 platelets	×0.00568	3.52 ± 1.32 nmol/10^9 platelets	208
Platelet-poor plasma	0.93 ± 0.67 ng/mL	×5.68	5.3 ± 3.8 nmol/L	198

can measure low concentrations of serotonin in different specimens.[140]

Serotonin can be measured in whole blood, serum, platelet-rich plasma, platelet-poor plasma (i.e., platelet-free plasma), isolated platelet pellets, urine, and CSF. Most blood serotonin is stored in the platelets and is easily released during sample preparation. For whole blood serotonin, venous blood (10 mL) is drawn into a tube containing potassium EDTA as an anticoagulant, gently mixed, placed on ice, and transferred to a storage tube. An aliquot of blood is then removed for a platelet count; alternatively, a simultaneous EDTA blood sample can be collected. Antioxidants such as ascorbic acid or metabisulfite are conveniently added to the storage tube when a fluorometric detection system is used. Blood serotonin samples are stored frozen at −20 °C, preferably within 2 hours after collection.

Platelet-rich plasma samples are prepared from whole blood by centrifuging at 120*g* for 30 minutes at 4 °C[171] or at 200*g* for 15 minutes at room temperature.[208] To prevent lowering the serotonin concentration, platelet-rich plasma is prepared within 1 hour after the blood is collected and placed on ice. An aliquot of platelet-rich plasma is removed for a platelet count. Platelet-poor plasma and platelet pellets are prepared from measured aliquots of the platelet-rich sample plasma by centrifuging at 4500*g* for 10 minutes at 4 °C[198] (or at 1000*g* for 30 minutes at room temperature).[208] To reduce the probability of platelet rupture, samples should never be frozen before the cell-free plasma is obtained. Plasma and pellets are stored frozen at −20 °C and analyzed within 1 to 2 weeks after collection.

Serum samples are conveniently collected in serum separation tubes (SST) tubes. Blood clotting releases serotonin from platelets; samples should be centrifuged within 1 hour after collection and stored frozen at −20 °C. Twenty-four-hour urine samples are collected in 2-L brown polypropylene bottles containing 250 mg each of sodium metabisulfite and EDTA as preservatives. Samples are acidified to pH 4 with acetic acid before freezing.

Whole blood measurement of serotonin is popular because time-consuming isolation of platelets is not required. In general, serotonin levels in whole blood, collected with EDTA anticoagulant, better represent peripheral blood concentrations than serum serotonin, although the latter are often recommended for pediatric patients. Whole blood serotonin concentrations, expressed in nmol/L, are higher while standing than supine because of an increase in platelets.[208] For meaningful comparisons, whole blood serotonin determinations should be corrected for platelet count. Several types of anticoagulants have been studied for their ability to prevent release of serotonin from platelets; potassium EDTA gave better results than citrate in platelet-free plasma.[174] Unlike 5-HIAA, serotonin measurements are not significantly influenced by short-term ingestion of serotonin-rich foods.[138] Platelet serotonin is age dependent; elderly subjects have higher values than newborns but lower values than children and adults.[75] Representative reference intervals are shown in Table 29-14 for biological fluids.

5-Hydroxyindoleacetic Acid (5-HIAA)

Qualitative and quantitative analyses of 5-HIAA in urine were first described in 1955. Historically, two photometric methods for qualitative screening were used. The nitroso-naphthol-nitrous acid procedure[86,246] was more specific and widely used than the dimethylaminobenzaldehyde (Ehrlich's aldehyde) procedure. These qualitative screening tests, however, are no longer recommended since they are insensitive and susceptible to interference.

Like serotonin, 5-HIAA is strongly fluorescent, and a number of fluorometric procedures have been developed for quantitative analysis. Fluorescence can then be measured directly or after derivatization with *o*-phthalaldehyde.

Rapid developments in analytical techniques have led to the introduction of more selective and sensitive methods for quantitating 5-HIAA in urine and plasma, including gas chromatography, immunoassay, HPLC, and liquid chromatography–tandem mass spectrometry (LC-MS–MS). At present, HPLC is the most widespread method for measuring 5-HIAA in the clinical laboratory and has largely replaced the photometric and fluorometric methods.

TABLE 29-15 Adult Reference Intervals for Plasma and Urinary 5-HIAA

Biological Sample	Mass Units	Conversion Factor	Molar Units	Reference
Urine	1-7 mg/d	×5.23	6-37 μmol/day	217
	0-6.6 mg/g creatinine	×0.592	0-3.9 μmol/mmol creatinine	231
Plasma	5.2-13.4 ng/L	×5.23	27-70 nmol/L	52

Numerous HPLC methods have been described for measuring 5-HIAA, either separately or in combination with other clinically interesting substances.[51] Most procedures employ reversed-phase, paired-ion separations under optimized isocratic conditions. Alkyl-bonded silica, such as octadecysilyl (C18), is often used as the hydrophobic stationary phase, and an organic-aqueous buffer mixture at an acid pH is frequently used as the polar mobile phase.

Electrochemical detection using amperometric or coulometric measurement is preferred for specific measurement of small quantities of 5-HIAA; a modification of the method developed by Chou and Jaynes[39] is is available on this book's accompanying Evolve site. Like serotonin, the oxidation potential for 5-HIAA is below 0.6 V and must be optimized for each application. Very few interfering compounds are electrochemically active at such low voltage potentials. But if detection of 5-HIAA with other indoles and catecholamines is desired, then hydrodynamic voltammograms for each analyte should be studied to select the minimum potential that achieves maximum specificity.[247] Some HPLC systems use fluorometric detection, with or without derivatization, for a less demanding measurement of 5-HIAA.[231] A method combining fluorometric and electrochemical detection has also been described.[236]

Preliminary extraction of 5-HIAA may be used as an initial purification step before HPLC analysis. Organic solvents, anion-exchange resins, and other solid phase extraction procedures have all been used.[253] For many systems, direct injection of urine onto the analytical column is a common practice,[15,101] and samples are often merely diluted with a buffer to protect the HPLC system from contamination. Methods that analyze 5-HIAA without prior sample cleanup rely on the selectivity of the HPLC separation combined with fluorescence or electrochemical detection to provide the requisite specificity.

For measurement of 5-HIAA in plasma, HPLC methods with electrochemical[261] or fluorescence detection[34] have been described. The latter uses diethyl ether for preliminary extraction of heparinized plasma. The internal standard and 5-HIAA are then separated by gradient elution on a C18 column and detected with a spectrofluorometer (excitation wavelength, 280 nm; emission wavelength, 345 nm). This method is linear to 190 ng/L, and the interassay precision, expressed as a coefficient of variation, is less than 6% at a 5-HIAA concentration of 30 ng/L.

Alternative technologies based on immunoassay and tandem mass spectrometry are available for quantitating 5-HIAA. A ready-to-use competitive EIA kit has been developed for measuring chemically derivatized 5-HIAA.[115] In this procedure, dichloromethane is used to convert 5-HIAA to its methyl ester during sample preparation. This methylated derivative competes with biotin-labeled 5-HIAA for a limited number of binding sites of an antibody immobilized on microtiter plates. After incubation, the wells are washed to remove unbound biotin-labeled HIAA and then incubated with antibiotin alkaline phosphatase before a p-nitrophenyl phosphate substrate is added. The amount of biotinylated HIAA bound to the antibody is inversely proportional to the 5-HIAA concentration. This EIA method shows excellent correlation with HPLC, and interassay reproducibility coefficient of variation (CV) is about 7% at a 5-HIAA level of 7.5 mg/L.

LC-MS–MS methods for the determination of 5-HIAA in urine have been developed.[145,162] one of which uses an automated solid phase extraction, isocratic LC elution, and quantification against a stable isotope-labeled internal standard.[145] With these procedures, sample preparation is automated, chromatographic interferences are eliminated, and analytical time is reduced (2 minutes per sample).

Sample collection and storage protocols are an important consideration in testing plasma or urine by the instrumental techniques discussed above. For determination of 5-HIAA in plasma, a blood specimen is collected with heparin as an anticoagulant after an overnight fast. The separated plasma is stored frozen at −20 °C until analysis, since plasma stored at 4 °C for 7 days showed an 8% average increase in 5-HIAA concentration.[34] For urinary measurement of 5-HIAA, a 24-hour specimen is recommended, since 5-HIAA concentrations in random urine are extremely variable. Shorter (or longer) collection times may be acceptable provided results are expressed per milligram of creatinine. Because 5-HIAA is light sensitive, urine should be collected in a 2-L brown polypropylene container. As 5-HIAA is unstable at alkaline pHs,[4] a stabilizing preservative is recommended to prevent urine from becoming alkaline (e.g., 0.5 g boric acid; 10 mL HCl, 6 mol/L; 25 mL glacial acetic acid). Most importantly, the specimen should be refrigerated during collection. On receipt in the laboratory, the urine specimen is thoroughly mixed and the total volume measured and recorded. If the specimen is not collected with an acid preservative, then the pH of the urine may now be adjusted to between 2 and 3 by addition of HCl, 6 mol/L. Acidified urine can be stored at 4 °C for 2 to 4 weeks and for longer periods of time at −20 °C.

Dietary instruction for the patient may reduce potential exogenous interferences. For example, dietary sources of 5-hydroxyindoles (e.g., walnuts, bananas, avocados, eggplants, pineapples, plums, and tomatoes) should be restricted 3 to 4 days before and during urine collection. If possible, patients should abstain from all known medications that may cause an apparent increase (glycerol guaiacolate, mephenesin, phenacetin, and acetaminophen) or decrease in 5-HIAA levels (methenamine, phenothiazine tranquilizers, homogentisic acid, acetic acid, and levodopa). Whereas serotonin-containing foods clearly alter urinary 5-HIAA results, fasting plasma 5-HIAA results are not affected by foods high in hydroxyindole content. Representative reference intervals used in the interpretation of plasma and urinary 5-HIAA are shown in Table 29-15.

CHAPTER 30

Vitamins and Trace Elements*

Alan Shenkin, Ph.D., Malcolm Baines, F.R.S.C., F.R.C.Path., Gordon S. Fell, Ph.D., F.R.C.Path., and T.D.G. Lyon, B.Sc., Ph.D.

Adequate supplies of vitamins and trace elements are extremely critical in maintaining the health and development of humans. These nutrients occupy the attention of those concerned with the physical well being of a public made increasingly aware of the need for the quality and the quantity of their dietary intake. The general principle regarding assessment of nutritional status is to determine the extent to which the metabolic demand for nutrients has been or is currently being met by the supply. In clinical practice, this requires balancing supply and demand.

Accurate assessment of supply and intake is a complex procedure. In practice, a crude estimate of intake can be obtained from a careful clinical history taken by an experienced practitioner or from a food frequency questionnaire that summarizes the content of the individual's diet over several days, depending on how frequently particular typical foods are consumed.[54] A more accurate quantitative assessment usually requires a minimum of three days recording of a complete dietary diary, which is subsequently analyzed using a computer program with reference tables of the nutritional contents of most foods.[414] Unfortunately, estimates of the portion size, amounts consumed, and actual nutritional composition of the food consumed may be inaccurate. In addition, the disease process also affects the amount actually consumed and absorbed, further reducing the accuracy of the estimate of nutritional intake.

Currently, the requirements for most nutrients to maintain health are now fairly well characterized and available in reports from the Institute of Medicine (IOM) of the National Academies (http://www.iom.edu).[170-174] However, the effects of disease may increase demands. For example, hypermetabolism, as a result of trauma or infection, increases the need for protein and energy[145,349] and for the vitamin and trace element cofactors necessary for their metabolism.[526] Increased losses from the gut, kidney, skin, or dialysis also may increase the overall demand for these nutrients.

An estimate of supply also is obtained from a careful dietary history, especially if performed by a dietician, together with knowledge of any artificial nutritional supplements or therapy that may have been provided enterally or intravenously. Table 30-1 summarizes the Recommended Dietary Allowance (RDA) made in the United States and the Population Reference Intakes (from the European community) for vitamins and trace elements. These levels are expected to be present in the normal diet of healthy adults. Table 30-1 also summarizes the range of amounts present in 2000 kcal of most tube feeds used in nutritional support. It is clear that the amounts used enterally are greater than the oral amounts recommended in health to meet the increased needs resulting from the preexisting deficiencies and increased ongoing requirements as a result of disease. The amounts recommended for supply during intravenous nutrition are also summarized in Table 30-1. For the trace elements, these amounts are generally less than the oral and/or enteral requirements to allow for the reduced absorption enterally. For the vitamins, these levels are usually greater than the oral and/or enteral requirements to allow for the effects of disease.

In an attempt to improve accuracy of assessment of nutritional status, clinicians often turn to the laboratory to

Reference intakes for infants and children are age and weight dependent and are summarized in various sources.[170,172,174,207,530]
RDA, Recommended dietary allowance (U.S.)[170,172,174]; *PRI*, population reference intake (Europe);[463] *PUFA*, polyunsaturated fatty acids.
*Adequate intake.
†Acceptable range.

provide a result that may reflect the net balance of supply and demand.[198,524,526] Clinical laboratorians need to be aware of where such tests are useful and how to place the results of laboratory tests into the context of the clinical situation of the patient.* It is important to be aware of the limitations of laboratory tests, especially in acutely ill patients.

NUTRITIONAL ASSESSMENT AND MONITORING

In this brief overview, the nutrients used in nutritional assessment and in monitoring will be briefly discussed.†

*A discussion of the Laboratory's role in nutritional assessement plus a number of case studies are available on this book's accompanying Evolve site, found at http://evolve.elsevier.com/Tietz/textbook/.

†A number of anthropometric and biochemical techniques and methods are used to assess nutritional status. They are discussed in an earlier edition of this textbook. (Veldee MS. Nutritional assessment, therapy, and monitoring. In: Burtis CA, Ashwood ER, eds. Tietz textbook of clinical chemistry, 3rd edition. Philadelphia: WB Saunders, 1999:1380-88.)

PROTEIN-ENERGY STATUS

In clinical practice, only a few laboratory tests are of value in the assessment of protein-energy status.[524,527] It is particularly important to recognize that serum protein concentrations are not helpful in sick patients with any form of inflammatory process (see Chapter 20). Although serum albumin is often measured and reported as an indicator of protein-energy status, factors such as increased transcapillary escape[164] and reduced hepatic synthesis make it of little value as a nutritional marker. Serum albumin is, however, a valuable prognostic marker and is frequently used as part of prognostic indices.[88] Short half-life proteins, such as transthyretin (prealbumin) also may be of some limited value in patients with no inflammatory response.[164,265]

Assessment of nitrogen balance may be used to provide information on recent protein-energy status. This requires careful 24-hour urine collection and estimation of total nitrogen content[213,313] or urea nitrogen (from which total nitrogen can usually be approximately estimated).[191] With a reasonable calculation of protein (nitrogen) intake, intake minus urine output (together with some unmeasured losses) gives an estimate of nitrogen balance. In practice, however,

such measurements are now rarely required except when (1) patients appear to have excessive losses, (2) they are failing to respond to what appears to be adequate nutritional support therapy, or (3) a novel therapy is being evaluated for its effectiveness in limiting catabolism or stimulating anabolism.

Vitamin and Trace Element Status

The measurement of vitamin and trace element levels is frequently helpful in nutritional assessment. The relative value of such tests is increased by the fact that clinical assessment of their status is often poor.

Although requirements for vitamins and trace elements are known in health (Table 30-1), the effects of illness on these requirements are poorly understood and quantified. However, it is now apparent that as an individual develops progressively more severe depletion in vitamin or trace element status, the person passes through a series of stages with biochemical or physiological consequences. The metabolic or physiological penalty of such suboptimal nutritional status is usually not clear, but the assumption remains that the suboptimal metabolism is likely to have detrimental effects (e.g., subclinical deficiency of folic acid is associated with an increase in serum homocysteine concentration, which is an independent risk factor for coronary artery disease—see Chapter 26).[607] Similarly, subclinical deficiency of chromium may be associated with impaired glucose tolerance in certain types of diabetes.[13]

The time course for the development of a subclinical deficiency state varies for each individual vitamin and trace element and depends on the nature and amount of body stores. Moreover, the extent of depletion necessary before there are significant biochemical, physiological, or histological changes is poorly characterized. The consequences of an inadequate intake are more clearly delineated in Figure 30-1. There is progression from optimal tissue status through a period of initial depletion until a period of subclinical deficiency is reached with a variety of biochemical and nonspecific physiological effects. In some cases there may also be certain nonspecific histological changes that may put the individual at risk of tissue damage or neoplastic change. It is only when there is a persistent mismatch of intake and demand that eventually a full-blown clinical deficiency state develops.

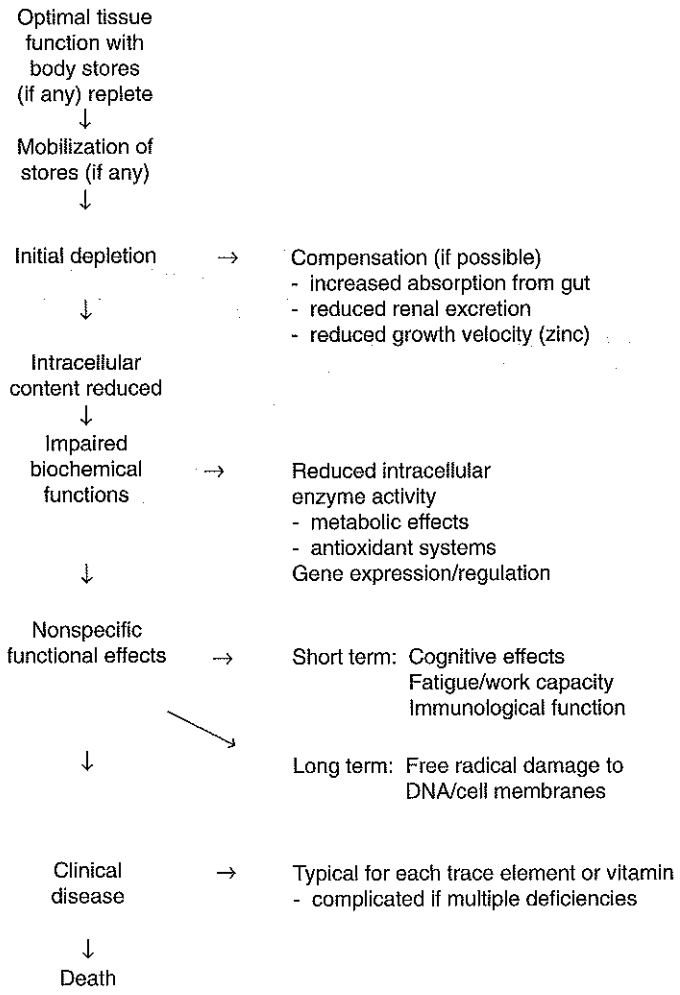

Figure 30-1 Consequences of inadequate mineral or trace element intake. *(From Shenkin A, Allwood MC. Trace elements and vitamins in adult intravenous nutrition. In: Rombeau JL, Rolandelli RH, eds. Clinical nutrition: Parenteral nutrition. Philadelphia: WB Saunders Co, 2001:60-79.)*

Enzymes or Metabolites

Determination of the effective functioning of particular enzymes or metabolic pathways potentially may be useful in demonstrating adequacy of provision. Enzymes in plasma that may be helpful in this regard are glutathione peroxidase as an index of selenium status, and red cell enzymes, such as transketolase (thiamine), glutathione reductase (riboflavin) or transaminase (pyridoxine), or glutathione peroxidase (selenium) are all widely used. Methyltetrahydrofolate reductase is involved in metabolism of homocysteine, hence assessment of plasma homocysteine is a useful measure of folate status through the indirect assessment of the action of this enzyme system.

Markers of Antioxidant Status

As it is practically impossible to measure all the biologically active antioxidants in human samples, the concept of a "global" assessment of antioxidant capacity has proved attractive.[223,224] A number of methods have therefore been developed to assess this capacity and for use in clinical research. Most of the methods use one of two main approaches to the measurement, either the quenching or delayed production of a stable, measurable radical species, or the reductant properties of the antioxidants against a radical cation or a metal ion.[499] These are usually standardized with the water-soluble vitamin E analogue Trolox. An example of the former is the total radical-trapping antioxidant parameter (TRAP) assay, which uses the stable radical species 2,2′-azinobis(3-ethylbenzthiazo-

linesulfonate) ($ABTS^+$) and an example of the latter is the ferric reducing ability of plasma (FRAP) assay.[43] Because these methods use different reaction principles, the same antioxidant can have different contributions to each assay, and it is for this reason that the use of more than one method is recommended for any study.[451] Vitamins that can contribute to plasma antioxidant capacity are ascorbate (up to 24% of the measured capacity), α-tocopherol (up to 10% of measured capacity), and β-carotene, though at typical plasma concentrations of around 0.5 μmol/L, the contribution of β-carotene—as with most fat-soluble vitamins—to a total antioxidant capacity of around 1000 μmol/L is minimal.

A disadvantage of many methods of total antioxidant capacity measurement is the variable contribution of common plasma constituents, particularly albumin and urate, to the measured concentration.[197] Changes in circulating concentrations of these molecules caused by acute phase changes or changes in renal function can alter measured values without reflecting changes in antioxidant vitamin concentration. This problem can be largely overcome by the use of the "antioxidant gap," a derived value that subtracts the Trolox equivalence of albumin and urate from the measured total antioxidant capacity.[389]

In an attempt to assess the functional adequacy of vitamins and trace elements involved in antioxidant pathways, products of oxidative metabolism can be measured. Those frequently used are malondialdehyde or F_2 isoprostanes, both of which give an indication of oxidation of polyunsaturated fatty acids within cells.[223] Increasing the provision of individual antioxidants or cocktails of vitamins and trace elements can lead to a reduction in production of these metabolites that can be measured in serum or urine. Such tests have not yet reached widespread application primarily because the interpretation of results is difficult. Also, knowledge of the appropriate amount of oxidative activity that is linked to particular outcomes has not yet been identified. This is especially important since there have been few clinical studies demonstrating benefit from provision of increased amounts of antioxidants.[42,167]

Analytical Factors

A number of analytical factors must be considered when assessing the status of each nutrient. They include reference intervals, concentrations of markers in plasma and tissue, and their measurement in urine.

Reference Intervals

As for all laboratory tests, interpretation of tests of nutritional status requires access to relevant reference intervals and an understanding of the factors that may alter them. Ethnic origin and geographic variation might affect the typical diet and its chemical composition, and the fiber or phytate content may alter the bioavailability of minerals. In early infancy, the liver matures, leading to an increase in serum copper, whereas dietary changes in milk and weaning are associated with changes in plasma selenium. Seasonal variations may alter the reference intervals of vitamins, especially vitamin D. Time of sampling is also important, since zinc and iron concentrations tend to be higher in fasting than fed individuals and are therefore usually lower in the afternoon.

Plasma Concentrations

Concentrations of vitamins and trace elements are measured most often in plasma or serum; this provides a reliable index of status for only a few of them (e.g., vitamin B_{12} or vitamin D). For others (e.g., folate or selenium), their concentrations only may reflect the adequacy of recent intake. An excessive provision of elements such as manganese and chromium may also be detected by high serum concentrations.[154,520]

For some vitamins or trace elements, serum measurement is limited in value, especially in seriously ill patients. This is partly a result of the lack of correlation between the amount of nutrient in the plasma compartment with the amount within the intracellular compartment in most body tissue. For example, there may be substantial stores of particular vitamins or trace elements in individual tissue (e.g., vitamin A in the liver), but mobilization into the plasma is affected by the availability of the appropriate binding proteins or by metabolism. Also, there are differences in the content of individual vitamins or trace elements between tissues, and the serum concentration will not reflect these differences. Furthermore, and particularly important, is the fact that the concentration in plasma can alter rapidly when an acute phase response (APR) to trauma or infection leads to redistribution of metals between body compartments[523]; there is increased synthesis of metallothionein, leading to the uptake of zinc into the liver, and increased synthesis of ferritin causing uptake of iron.[119,475] The result is a fall in plasma concentration of both zinc and iron. These changes in plasma concentration clearly do not reflect changes in whole body status.

There are also changes in the binding proteins in plasma as a result of the disease process. Since serum albumin falls in association with any acute illness, this inevitably leads to a fall in plasma zinc concentration. Similarly a reduction in retinol-binding-protein concentration as part of the APR or protein malnutrition also leads to a fall in serum retinol levels, whatever the amount of retinol stores within the liver.

Some patients may be relatively stable, with little APR to injury, infection, or other inflammatory disease. If this is the case, it may be possible to interpret the plasma concentrations of elements such as zinc, copper, and iron, or vitamins such as vitamin C or B_6 that would all be affected by an APR.[347] Of particular relevance is the trend in concentration of a trace element or vitamin in relation to the magnitude of the APR changes. Repeated measurements of a rapid response acute phase protein, such as C-reactive protein (CRP), together with trace elements, may therefore be helpful as part of the nutritional assessment.

Tissue Concentrations

Tissue concentrations of vitamins or trace elements are rarely measured in nutritional assessments because of the lack of availability of suitable tissue; however, where such tissue is available, measurement may be helpful (e.g., copper analysis on liver biopsy of patients with suspected Wilson's disease).

More commonly, certain types of cells from blood samples may be obtained and can provide useful information. For example, red cell folate is commonly used as a marker of folate status, and leukocyte vitamin C is a better marker of vitamin C status than plasma concentration.[495] Because of the difficulty of preparation of pure populations of cells, cellular measurements are usually only used within a research environment.

Urine Measurements

For most vitamins and trace elements, their measurement in urine is rarely helpful since most are not under homeostatic control, and excretion may be a direct reflection of intake rather than active retention in the face of whole body deficiency. High levels of excretion of certain water-soluble vitamins or trace elements may indicate ingestion of large amounts of supplements.

VITAMINS

Vitamins are organic compounds required in trace amounts (in microgram to milligram quantities per day) in the diet for health, growth, and reproduction. It is commonly understood that vitamins are natural materials that can be isolated from organisms (such as plants that can synthesize most of these compounds) or that can be chemically synthesized. Additionally, there are synthetic analogues and derivatives of vitamins designed to serve as inhibitors (e.g., amethopterin as an antifolate) and others that substitute in part for the natural vitamin (e.g., 8-ethylriboflavin for riboflavin). Only small amounts of vitamins are required for the functional, often catalytic (co-enzymatic) roles they serve, in contrast to the relatively large amounts of such macronutrients as protein, lipid, and carbohydrate, which constitute the bulk of the ingesta that serve primarily as sources for energy and reconstitution of body mass.

Historically, vitamin groups such as A, B, and D bear an Arabic subscript number following the letter either to designate structural and functional similarity (e.g., A_1 [retinol] and A_2 [3-dehydroretinol]) or to indicate the approximate order in which they are identified as the members of the so-called B-complex (e.g., B_1 [thiamine] and B_2 [riboflavin]). Common chemical names, which are receiving greater use, give a better indication of the types of compounds involved. These often reflect the presence of some specific atom (*thia*mine), prime functional group (pyridox*amine*), or even a larger portion of the molecular structure (phyllo*quinone*). Parts of some names reflect functional properties (chole*calciferol*).

Another classification pertains to the relative solubility of vitamins. Those of the "fat-soluble" group (A, D, E, and K) are more soluble in organic solvents, whereas the B-complex group vitamins and vitamin C are "water soluble." This general separation based on solubility is useful not just for purposes of noting gross physical properties but also as a reminder that the fat-soluble vitamins are absorbed, transported, and stored for longer periods of time and in a manner generally similar to that for fats. Most water-soluble vitamins share the fate of other solutes more compatible with an aqueous, physiological medium; this includes a lesser tendency to be retained for long periods of time in the body and a greater loss by way of urinary excretion. Additionally a general functional difference also exists, since the water-soluble vitamins function as coenzymes for several important enzymatic reactions in both mammals and microorganisms. By contrast, the fat-soluble vitamins generally do not function as coenzymes and are rarely used by microorganisms.

Table 30-2 provides a list of 13 known vitamins and vitameric groups essential to humans.

VITAMIN A

Vitamin A serves many important functions in the body, with its role in vision being of particular significance.

Chemistry

Vitamin A is the nutritional term for the group of compounds with a 20-carbon structure containing a methyl-substituted cyclohexenyl ring (β-ionone ring) and an isoprenoid side chain (Figure 30-2), with either a hydroxyl group (retinol), an aldehyde group (retinal), a carboxylic acid group (retinoic acid), or an ester group (retinyl ester) at the terminal C15.

Retinol, the principal vitamin A vitamer, can be oxidized reversibly to retinal—which shares all the biological activity of retinol—or further oxidized to retinoic acid, which shows some of its biological activity. The principal storage forms of vitamin A are retinyl esters, particularly palmitate. The term retinoids refers to retinol, its metabolites, and synthetic analogues with similar structure. Included in the vitamin A family are some dietary carotenoids (C40 polyisoprenoid compounds) that are classified as provitamin A because they are cleaved biologically to yield retinol. Although around 1000 compounds with carotenoid structure have been identified,[366] only around 50 possess provitamin A activity, with the principal dietary compounds being β-carotene, α-carotene, and β-cryptoxanthin. Vitamin A compounds are yellowish oils or low-melting-point solids (depending on isomeric purity) that are practically insoluble in water but soluble in organic solvents and mineral oil. Vitamin A is sensitive to oxygen and ultraviolet light, which induces a greenish fluorescence with an absorbance peak at 325 nm. The structure for the most common and effective provitamin A, β-*carotene*, is also given in Figure 30-2. This compound is an orange-to-purple, water-insoluble solid that is oxidized in

TABLE 30-2 Vitamins Required by the Human

Common Name	Trivial Chemical Name	General Roles	Symptoms of Deficiency or Disease	Direct and Indirect Assays
Fat Soluble				
Vitamin A	Retinol, retinal, retinoic acid	Vision, growth, reproduction	Nyctalopia, xerophthalmia, keratomalacia	Photometric, HPLC, fluorimetric, RIA
Vitamin D_2, D_3	Ergocalciferol Cholecalciferol	Modulation of Ca^{2+} metabolism, calcification of bone and teeth	Rickets (young), osteomalacia (adult)	CPB, HPLC, RIA
Vitamin E	Tocopherols, tocotrienols	Antioxidant for unsaturated lipids, neurological and reproductive functions	Lipid peroxidation, including red blood cell fragility, hemolytic anemia (premature, newborn)	Photometric, HPLC, erythrocyte hemolysis
Vitamin K_1, K_2	Phylloquinones Menaquinones	Blood clotting, osteocalcins	Increased clotting time, hemorrhagic disease (infant)	HPLC, prothrombin time, RIA (abnormal prothrombin, PIVKA Test)
Water Soluble				
Vitamin B_1	Thiamine	Carbohydrate metabolism, nervous function	Beriberi, Wernicke-Korsakoff syndrome	Fluorimetric, transketolase, HPLC
Vitamin B_2	Riboflavin	Oxidation-reduction reactions	Angular stomatitis, dermatitis, photophobia	Fluorimetric, HPLC, glutathione reductase
Vitamin B_6	Pyridoxine, pyridoxal, pyridoxamine	Amino acid, phospholipid, and glycogen metabolism	Epileptiform convulsions, dermatitis, hypochromic anemia	HPLC, aspartate transaminase, urine pyridoxic acid
Niacin niacinamide	Nicotinic acid, nicotinamide	Oxidation-reduction reactions	Pellagra	Fluorometric, HPLC, nicotinamide coenzymes
Folic acid	Pteroylglutamic acid	Nucleic acid and amino acid biosynthesis	Megaloblastic anemia, neural tube defects	CPB, microbiological, homocysteine
Vitamin B_{12}	Cyanocobalamin	Amino acid and branched-chain keto acid metabolism	Pernicious and megaloblastic anemia, neuropathy	CPB, microbiological, RIA, methylmalonate
Biotin	—	Carboxylation reactions	Dermatitis	Microbiological, CPB, carboxylases, avidin binding
Pantothenic acid	—	General metabolism, acetyl and acyl transfer	Burning feet syndrome	Microbiological, RIA, CPB/HPLC
Vitamin C	Ascorbic acid	Connective tissue formation, antioxidant	Scurvy	Photometric, HPLC, enzymatic

HPLC, High-performance liquid chromatography; *RIA*, radioimmunoassay; *CPB*, competitive protein binding; *PIVKA Test*, proteins induced by or involved in vitamin K antagonism or absence.

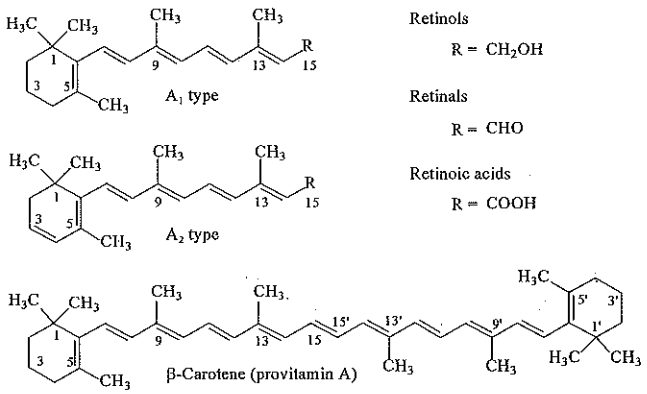

Figure 30-2 Vitaminic forms of A_1, A_2, and β-carotene.

air to inactive products. The other carotenes, cryptoxanthin and β-apocarotenals, are asymmetrical with only one β-ionone ring and yield less vitamin A activity.

Dietary Sources

Preformed vitamin A is obtained from animal-derived foods such as liver, other organ meats, and fish oils. Other sources are full cream milk, butter, and fortified margarines. The provitamin A carotenoids are obtained from yellow to orange pigment fruits and vegetables, and green leafy vegetables. Good sources are pumpkin, carrots, tomatoes, apricots, grapefruit, lettuce, and most green vegetables.[359] The U.S. National Health and Nutrition Examination Survey (NHANES-II) indicated that approximately 25% of the vitamin A requirement was provided by carotenoids and about 75% by preformed retinol.[59]

Absorption, Transport, Metabolism, and Excretion

Preformed vitamin A, most often in the form of retinyl ester, or carotenoids are subject to emulsification and mixed micelle formation by the action of bile salts before being transported into the intestinal cell. Here the retinyl esters are moved across the mucosal membrane and hydrolyzed to retinol within the cell to then be reesterified by cellular retinol-binding protein II and packaged into chylomicra, which then enter the mesenteric lymphatic system and pass into the systemic circulation.[409] A small amount of the ingested retinoid is also converted into retinoic acid in the intestinal cell. The efficiency of absorption of preformed vitamin A is high at between 70% and 90%.[533]

Carotenoids, also in micellular form, are absorbed into the duodenal mucosal cells by passive diffusion. The efficiency of absorption of carotenoids is much lower than for vitamin A, between 9% and 22%,[423] and is subject to a large number of variables, including carotenoid type, the amount in the meal, matrix properties, nutrient status, and genetic factors.[560] Once inside the mucosal cell, β-carotene is principally converted to retinal by the enzyme β-carotene-15, 15′-dioxygenase, the retinal being converted by retinal reductase to retinol and esterified, though it can also be cleaved eccentrically to β-apocarotenals, which can be further degraded to retinal or retinoic acid. The newly synthesized retinyl esters, from both preformed vitamin A and carotenoids, along with exogenous lipids and nonhydrolyzed carotenoids then pass with chylomicrons via the lymphatic system to the liver, where uptake by parenchymal cells again involves hydrolysis. In the liver, retinol is bound with retinol-binding protein (RBP, MW ~ 21,000 Da) and transthyretin (thyroxine-binding prealbumin) (MW ~ 55,000 Da) in a 1 : 1 : 1 complex of sufficient size to prevent loss by glomerular filtration and returned to the circulation, or it is stored as esters in the stellate cells. Delivery of retinol to the tissue is controlled by the availability of the vitamin A–protein complex in the circulation, though this control mechanism can be bypassed by large doses of retinol.

Retinoic acid from the intestinal mucosa is transported bound to serum albumin via the portal vein. Retinoic acid cannot be significantly reduced to retinal but is rapidly metabolized in tissue, such as liver, to yield more polar catabolites (e.g., 5,6-epoxyretinoic acid) and conjugates, such as retinoyl β-glucuronide, that are excreted. A small amount of retinoic acid undergoes enterohepatic circulation after intestinal hydrolysis of the glucuronide is excreted in the bile.

Functions

The participation of retinal in vision is considered the most important physiological function of vitamin A. All-*trans*-retinol is the predominant circulating form of vitamin A. Cells of the retina isomerize this to the 11-*cis* alcohol that is reversibly dehydrogenated to 11-*cis* retinal. This sterically hindered geometrical isomer of the aldehyde combines as a lysyl-linked Schiff base with suitable proteins (e.g., opsin) to generate photosensitive pigments such as rhodopsin. Illumination of such pigments causes photoisomerization and the release of all-*trans*-retinal and the protein, a process that couples the large conformational change to ion flux and optic nerve transmission. The all-*trans*-retinal is isomerized to the 11-*cis* isomer, which again combines with the liberated protein to reconstitute the photo pigment in a visual cycle shown in Figure 30-3. The pyridine nucleotide-dependent dehydrogenase (reductase) can also reduce the all-*trans*-retinal to all-*trans*-retinol.

Other functions of vitamin A include its role in reproduction, growth and embryonic development, and immune function, many of them mediated through the binding of retinoic acid to specific nuclear receptors that regulate genomic expression. In normal growth, and in the maintenance of the integrity of epithelial cells, retinoic acid acts through the activation of retinoic acid receptors (RAR) and retinoid X receptors (RXR) in the nucleus to regulate various genes that encode for structural proteins, enzymes, extracellular matrix proteins, and RBPs and receptors.[361] In vertebrate embryonic development, vitamin A requirement (mediated via RARs and RXRs) begins at the time of formation of the primitive heart circulation and specification

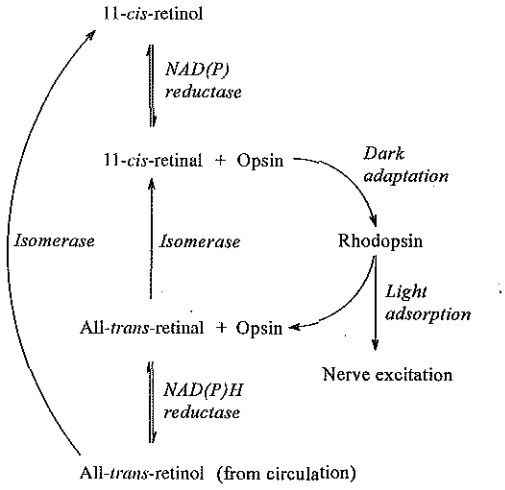

Figure 30-3 Participation of A vitamers in the visual cycle.

of the hindbrain,[639] and is later required for normal development of the limbs, heart, eyes, and ears.[134] Vitamin A deficiency impairs innate immunity by impeding normal regeneration of mucosal barriers damaged by infection, and by diminishing the function of neutrophils, macrophages, and natural killer cells. It is also required for adaptive immunity and plays a role in the development of both T-helper cells and B cells.[546] Retinol, its metabolites and synthetic retinoids, have protective effects against the development of certain types of cancer by blocking tumor promotion, by inhibiting proliferation, by inducing apoptosis, by inducing differentiation, or by a combination of these actions.[420] Finally, synthetic retinoids have been used successfully, both topically and systemically, to treat severe acne and other skin disorders of abnormal keratinization.

Some caution is required, however, regarding the use of vitamin A or β-carotene supplements since they appear to be of no benefit in reducing the incidence of gastrointestinal cancer and indeed may increase the incidence of lung cancer and mortality in certain other cancers.[55a,432a,566a]

Requirements and Reference Nutrient Intakes

Historical studies in adult humans have suggested that intakes of retinol of 500 to 600 μg/day are required to maintain adequate blood concentrations and to prevent all deficiency symptoms. The relative contribution of β-carotene and other provitamin A carotenoids to achieving this goal has undergone much revision as our knowledge has developed. In the older system of international units (IU), now largely redundant, a ratio for equivalence of activity of 1:2:4 for retinal:β-carotene : other provitamin A carotenoids was used, but this was superseded in 1967 by the retinol equivalent (RE), devised by a Food and Agriculture/World Health Organization (WHO) Expert Committee and proposing an equivalence ratio of 1:6:12. However, a 1999 study using stable isotopes of β-carotene[268] and a subsequent 2003 study[593] led the Food and Nutrition Board of the U.S. Institute of Medicine to recommend the retinol activity equivalent (RAE) as the basis of calculation of retinol intake. In this system, a ratio equivalence of 1:12:24 is recommended (i.e., 12 μg β-carotene or 24 μg mixed carotenoids has the same biological activity as 1 μg retinol). Using this system, current RDAs for vitamin A are 900 μg RAE for men 19 years and older; 700 μg RAE for women 19 years and older, with up to 770 μg RAE/day in pregnancy and up to 1300 μg RAE/day in lactation; 300 to 900 μg RAE for children 1 to 18 years, dependent upon age and sex; and for infants an adequate intake (AI) of 400 μg RAE at 0 to 6 months and 500 μg RAE from 7 to 12 months.[174]

Intravenous Supply

The recommended provision of vitamin A to adults during intravenous nutrition (IVN), whether this is partial or total parenteral nutrition (TPN), is 1000 μg retinol. This is usually provided as retinol palmitate and is supplied either with other fat-soluble vitamins in a mixture dissolved in a fat emulsion for intravenous feeding or is designed to be compatible with a mixture of all vitamins suitable for addition to other water-soluble nutrients.[519]

Deficiency

Vitamin A deficiency primarily affects infants and children, and its prevalence is subject to WHO surveillance.[627] Risk factors include poverty, low birth weight, poor sanitation, malnutrition, infection, and parasitism. Because hepatic accumulation of vitamin A occurs during the last trimester of pregnancy, preterm infants are relatively vitamin A deficient at birth. Providing a daily oral intake of vitamin A that meets the RDA of 400 μg RAE is therefore important. Infants with birth weights of less than 1500 g (those under 30 weeks gestation) have virtually no hepatic vitamin A stores and are at risk of vitamin A deficiency. Shenai and co-workers[518] and others[68,206] have observed that (1) bronchopulmonary dysplasia (BPD), a debilitating, chronic lung disease that mimics some histological features of vitamin A deficiency, is common; (2) intramuscular injections of 630 μg RAE every 2 days can reduce the incidence of BPD; (3) vitamin A (retinol) delivered in TPN solutions may be adsorbed into the inner walls of the plastic administration sets; however, this loss can be minimized by the use ethylene vinyl acetate rather than polyvinyl chloride; (4) blood levels of vitamin A decline during TPN, often reaching concentrations of 10 to 15 μg/dL (normal, 20 to 65 μg/dL) unless adequate supplements are given.

Fat malabsorption, particularly caused by celiac disease or chronic pancreatitis, and protein-energy malnutrition predispose to vitamin A deficiency. Liver disease diminishes RBP synthesis, and ethanol abuse leads both to hepatic injury and to a competition with retinol for alcohol dehydrogenase, which is necessary for the oxidation of retinol to retinal and retinoic acid.[328] Vitamin A deficiency may lead to anemia, though the precise mechanism is not known.[513]

The clinical features of vitamin A deficiency are degenerative changes in eyes and skin, and poor dark adaptation or *night blindness* (nyctalopia) followed by degenerative changes in the retina. X*erophthalmia,* in which the conjunctiva becomes dry with small gray plaques with foamy surfaces (Bitot's spots), develops. These lesions are reversible with vitamin A administration. More serious effects of deficiency are known as *keratomalacia* and cause ulceration and necrosis of the cornea that lead to perforation, prolapse, endophthalmitis, and blindness. Usually, there are associated skin changes, which include dryness, roughness, papular eruptions, and follicular hyperkeratosis. The general change is atrophy of certain specialized epithelia, followed by metaplastic hyperkeratinization.

Toxicity

Although vitamin A metabolism is tightly regulated, toxic effects of hypervitaminosis A can occur as a result of ingestion of excess vitamin or as a side effect of inappropriate therapy.[620] Hypervitaminosis A occurs after the liver storage of retinol and its esters exceeds 3000 μg/g tissue, after ingestion of greater than 30,000 μg/day for months or years, or if plasma vitamin A levels exceed 140 μg/dL (4.9 μmol/L). The elderly are more susceptible to vitamin A toxicity at lower doses, as exposure to retinyl esters is longer because of delayed postprandial clearance of lipoproteins.[483] Symptoms of acute toxicity from a single massive dose present as abdominal pain, nausea, vomiting, severe headaches, dizziness, sluggishness, and irritability, followed within a few days by desquamation of the skin and recovery. Chronic toxicity from moderately high doses taken for protracted periods is characterized by bone and joint pain, hair loss, dryness and fissures of the lips, anorexia, benign intracranial hypertension, weight loss, and hepatomegaly. The administration of doses up to threefold the RDA for several years resulted in classic histological changes of hepatotoxicity in 41 patients.[195] Infants given excess vitamin A over months to years can develop intracranial features, typically bulging fontanelle, and skeletal abnormalities at doses of 5500 to 6750 μg/day.[439]

Epidemiological and experimental evidence has supported the view that high vitamin A intake in humans, acting via 13-*cis*-retinoic acid, is teratogenic.[318] The critical period of susceptibility is the first trimester of pregnancy, and the primary abnormalities derive from the cranial neural crest (CNC) cells. A 1995 study of almost 23,000 pregnant women found that those who ingested more than 4500 μg/day of preformed vitamin A were at greater risk of delivering infants with malformations of CNC cell origin than women consuming less than 1500 μg/day.[478] A further intriguing association, supported in part by epidemiological studies, is that between excessive vitamin A intake and reduction in bone mineral density (BMD). Two studies of 175 Scandinavian women showed that a consistent loss in BMD at 4 sites was associated with increased preformed vitamin A intake.[376,386] Intake levels of vitamin A exceeding 1500 μg/day were associated with these changes, although 2 U.S. studies showed no increased bone mineral loss at preformed vitamin A intakes of up to 2000 μg/day.[183,257]

The findings of these and other studies have led the Food and Nutrition Board of the U.S. Institute of Medicine to recommend a tolerable upper intake level of 3000 μg/day of preformed vitamin A for men of 19 years and older, with lower levels for women of child-bearing age, infants, children, and adolescents. Carotenemia results from a chronic excessive intake of carotene-rich foods, principally carrots. This condition, in which yellowing of skin is observed, is benign, because the excess carotene is deposited rather than converted to vitamin A.

Laboratory Assessment of Status

Although measurement of the plasma concentration of vitamin A is the most convenient and widely used assessment of vitamin A status, it is not an ideal indicator because it does not decline until liver stores become critically depleted, which is thought to be at a concentration of approximately 20 μg/g liver. Early chemical methods, which may remain in use if high-performance liquid chromatography (HPLC) is not available, include the Carr-Price photometric method, which uses antimony trichloride in chloroform as the reagent, and the later Neeld-Pearson method, which uses trifluoroacetic acid to produce a blue pigment with the conjugated double bonds of vitamin A (and the carotenoids). Both methods use volatile or corrosive reagents, are nonspecific for vitamin A, are time consuming and difficult to automate, and require large sample volumes. To improve specificity and sensitivity, later methods used solvent extraction and other separation techniques, with fluorometric or spectrophotometric measurement.[585] HPLC has brought enhanced (1) specificity, (2) lowered limit of detection (less than 0.07 μmol/L), (3) accuracy (using primary standards, reference materials, and quality assurance schemes), and (4) reproducibility (between batch coefficients of variation of 10% or better).[572] Both normal-phase and reverse-phase techniques have been used.[109,373]

In the normal-phase HPLC, compounds to be separated are adsorbed to microparticulate silica gel and eluted in the order of least polar to most polar. Acceptable separation and quantitative yields of neutral and charged retinoids are obtained. Reverse-phase HPLC is preferable for acid-sensitive compounds such as 5,6-epoxyretinoic acid. Photometric, electrochemical, and mass spectrophotometric detectors have been used.

As retinol circulates in plasma as a 1:1:1 complex with RBP and transthyretin, both of these hepatically produced proteins have been measured as an indicator of vitamin A status. RBP has been measured by radial immunodiffusion or nephelometry (see Chapter 20), but its circulating concentration may be limited by inadequate dietary protein, energy, or zinc, all of which are necessary for RBP synthesis. Another confounding factor in the assessment of vitamin A status is the effect of the APR. Both RBP and transthyretin

are negative acute phase proteins and thus inflammatory changes will result in transient falls in both proteins and in plasma retinol. To distinguish inflammatory from nutritional causes of reduced plasma retinol concentrations, it may be necessary to measure high-sentivity CRP.[510]

Because circulating retinol concentrations do not always correlate with total body stores of vitamin A, indirect tests have been employed to assess these stores. The relative-dose-response test, described first by Loerch et al,[341] requires 2 blood samples to be collected, one before and one 5 hours after a physiological dose of vitamin A. In vitamin A–depleted subjects there is a rapid, large, and sustained rise in serum retinol concentration, which contrasts with a lower, more shallow rise in vitamin A–sufficient subjects. A modified-relative-dose-response test (using 3,4 didehydroretinyl [DR] acetate rather than retinyl acetate and measuring the DR/retinol ratio after 5 hours) has been used by other workers to assess the vitamin A status of preschool Indonesian children[561] of lactating and nonlactating Indonesian women[562] and also in a population of well-nourished American children.[563] Quantitative assessment of total body stores may be made by using deuterated-retinol-dilution techniques, but these require long periods (about 3 weeks) for equilibration. In 2003 Ribaya-Mercado and colleagues developed a predictive mathematical formula that does not require serum isotope equilibration, allowing blood sampling to be made 3 days after isotope dosing.[466]

Reference Intervals

Guidance reference intervals for serum vitamin A are 20 to 40 μg/dL (0.70 to 1.40 μmol/L) for 1- to 6-year-old children; 26 to 49 μg/dL (0.91 to 1.71 μmol/L) for 7- to 12-year-old children; 26 to 72 μg/dL (0.91 to 2.51 μmol/L) for 13- to 19-year-old adolescents; and 30 to 80 μg/dL (1.05 to 2.80 μmol/L) for adults.[339,574] Values above 30 μg/dL (1.05 μmol/L) are associated with appreciable reserves in the liver and correlate well with vitamin A intake. Within the reference interval, values for men are generally about 20% higher than those for women.

By HPLC, the reference interval for serum β-carotene is 10 to 85 μg/dL (0.19 to 1.58 μmol/L).[574] Elevated levels are found in hypothyroid patients in whom conversion to vitamin A is decreased and in patients with hyperlipemia associated with diabetes mellitus.

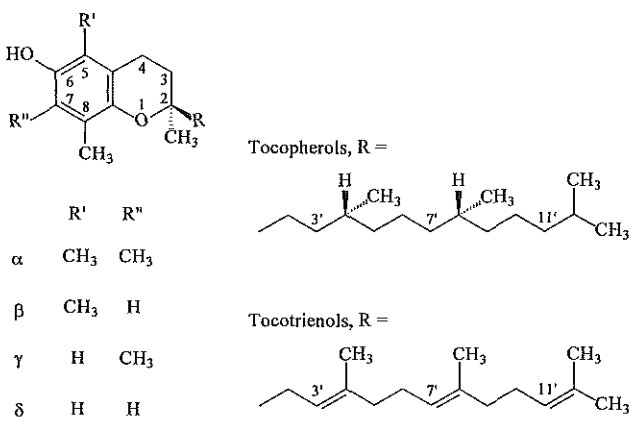
Vitamin D

Vitamin D plays an essential role as a hormone in the control of calcium and phosphorus metabolism. It is discussed in detail in Chapter 49.

Vitamin E

Vitamin E in an antioxidant that acts as a scavenger for molecular oxygen and free radicals. It also has a role in cellular respiration.

Chemistry



Vitamin E is the nutritional term for the group of naturally occurring tocopherols and tocotrienols that have biological activity similar to RRR-α-tocopherol (formerly d-α-tocopherol).[385] Both groups have a common 6-chromanol nucleus substituted with methyl groups at positions 2 and 8 and with a phytyl tail of isoprenoid units at position 2. The isoprenoid chain is saturated in the tocopherols, but unsaturated at positions 3′, 7′, and 11′ for tocotrienols (Figure 30-4). The Greek letter prefixes α, β, γ, and δ indicate the presence or absence of methyl groups at positions 5 and 7. The tocopherols have three asymmetric carbon atoms in the isoprenoid chain, giving eight optical isomers. The naturally occurring tocopherols occur as the RRR forms, whereas the synthetic compounds are of the racemic SR forms. Synthetic vitamin E contains about 12.5% of RRR-α-tocopherol together with seven other tocopherol isomers that are less biologically active. Tocopherol and tocotrienols are viscous oils at room temperature, soluble in fat solvents, and insoluble in aqueous solutions although there exists a water-soluble analogue (Trolox-6-hydroxy-2, 5, 7, 8-tetramethylchroman-2-carboxylic acid). Also, tocopherol and tocotrienols are stable to acid and heat in the absence of oxygen, but labile to oxygen in alkaline solutions and to ultraviolet light.

Dietary Sources

The principal sources of dietary vitamin E are oils and fats, particularly wheat germ oil and sunflower oil, grains, and nuts.[33] Meats, fruits, and vegetables contribute little vitamin E. Gamma-tocopherol is the major form of vitamin E in many plant seeds in the U.S. diet, but is present at only one quarter to one tenth of the concentration of α-tocopherol in human plasma.[282,286]

Absorption, Transport, Metabolism, and Excretion

In the presence of bile, vitamin E is absorbed from the small intestine.[107] Most forms of vitamin E are absorbed nonselectively and are secreted in chylomicron particles along with triacylglycerol and cholesterol. Some of this chylomicron-

δ	H	H

Figure 30-4 Vitaminic forms of vitamin E.

bound vitamin E is transported and delivered to the peripheral tissue (mainly adipose tissue) with the aid of lipoprotein lipase. The liver takes up the chylomicron remnants where the α-tocopherol is incorporated into very low-density lipoprotein (VLDL)s by α-tocopherol transfer protein (α-TTP), enabling further distribution of α-tocopherol throughout the body. Plasma vitamin E is further delivered to the tissue by low-density lipoprotein (LDL) and high-density lipoprotein (HDL).[286] The specificity of α-TTP for α-tocopherol is probably responsible for its preferential storage in most tissue. Vitamin E is excreted via the bile, in the urine as tocopheronic acid and its β-glucuronide conjugate, as carboxyethyl hydroxychromans (CEHC), and by unknown routes.[507] Degradation of vitamin E has been reviewed by Brigelius-Flohe and colleagues.[75]

Functions

Historically, vitamin E has been recognized as necessary for neurological and reproductive functions, for protecting the red cell from hemolysis, and for prevention of retinopathy in premature infants.[75] Inhibition of free-radical chain reactions of lipid peroxidation is the most thoroughly defined role of vitamin E.[285] This occurs mainly within the polyunsaturated fatty acids of membrane phospholipids. Tocopherols and tocotrienols inhibit lipid peroxidation largely because they scavenge lipid peroxyl radicals faster than the radical can react with adjacent fatty acid side chains or membrane proteins. The resultant tocopheryl or tocotrienyl radicals may then react with further peroxyl radicals to produce tocopherones (nonradicals), or be regenerated by transferring an electron to ascorbate to form the ascorbyl radical. Thus vitamins E and C act synergistically to reduce lipid peroxidation (Figure 30-5).[102] Many epidemiological surveys have shown an association between reduced vitamin E intake (and other dietary factors) and increase in chronic disease incidence, particularly cardiovascular disease and cancer,[196,310,468,543] though intervention studies have produced mixed results. The Cambridge Heart Antioxidant Study[545] showed a significant 47% reduction in nonfatal myocardial infarction (MI) in the vitamin E treatment (400 or 800 IU per day) arm of a placebo-controlled study involving subjects with existing heart disease, whereas the Gruppo Italiano Studio Sopravvivenza Infarcto (GISSI) trial,[215] also involving secondary prevention, produced only a small but insignificant reduction in risk of death, nonfatal MI, or stroke in those given 300 mg per day of synthetic vitamin E versus the

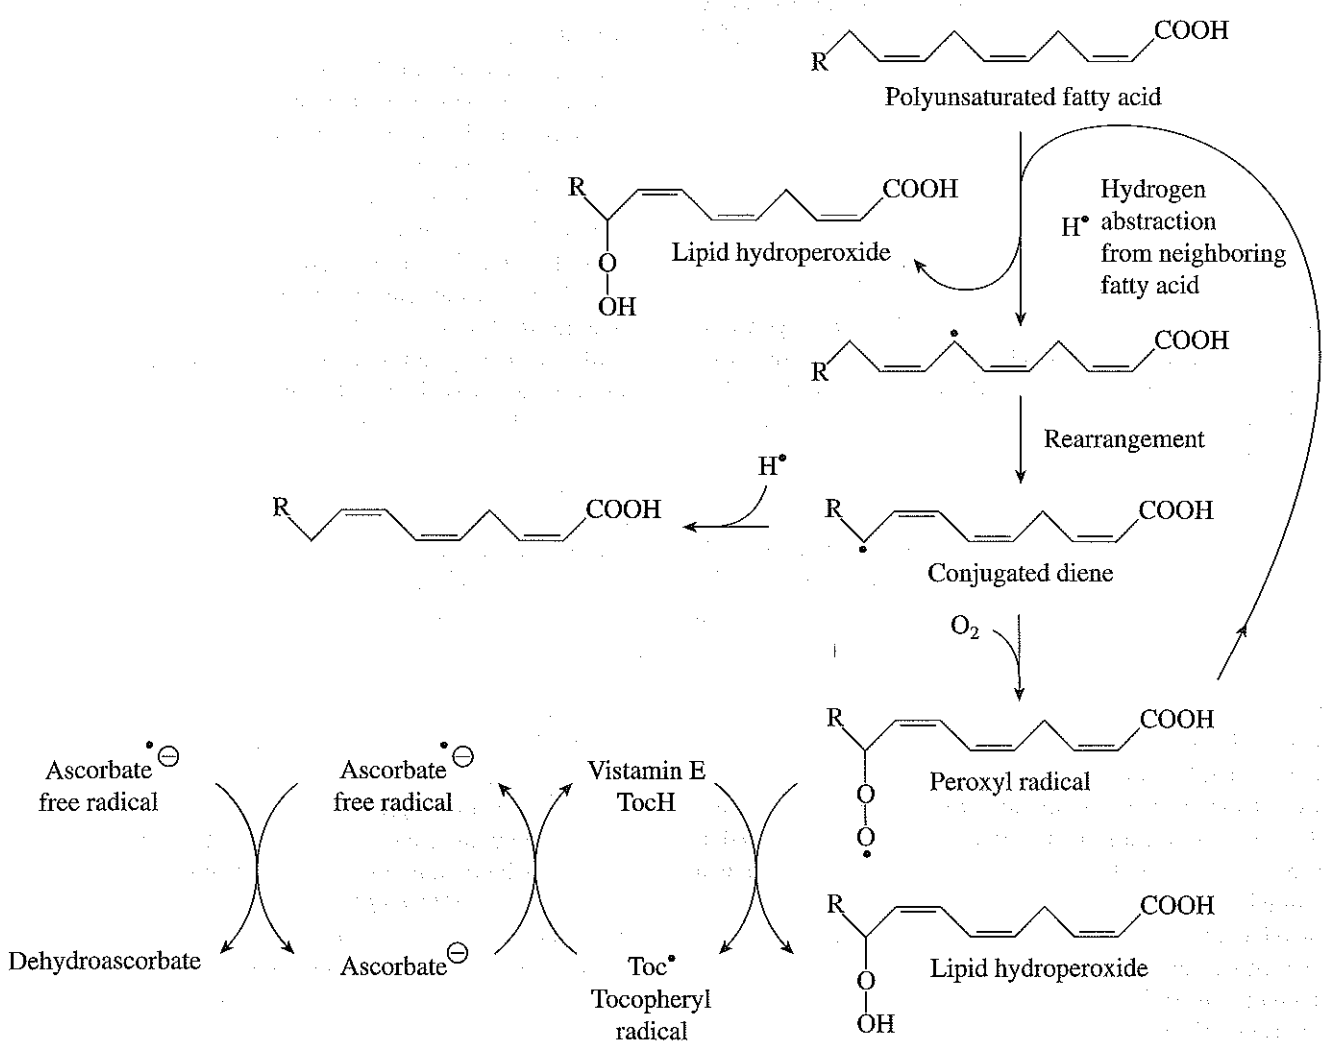

Figure 30-5 Lipoperoxidation and synergistic action of vitamin E and ascorbate.

control group. In 2002 the UK Heart Protection Study of 20,536 subjects with existing coronary disease, other occlusive disease, or diabetes showed that supplementation with vitamin E (600 mg), vitamin C (250 mg), and β-carotene (20 mg) during a period of 5 years produced no significant reduction in any type of vascular disease, cancer, or other major outcome, when compared with placebo.[240] A meta-analysis of clinical trials suggests that the response to vitamin E may be dose dependent—trials using 400 mg or less showed very slight or no benefit, whereas those using more than 400 mg per day showed a significant increase in all cause mortality.[387a] Any influence of vitamin E on disease progression may therefore be in primary prevention rather than secondary intervention, but there is also growing concern about possible harmful effects of high dose supplements.

Beyond its antioxidant properties, α-tocopherol inhibits protein kinase C and 5-lipoxygenase and activates protein phosphatase 2A and diacylglycerol kinase at the posttranslational level. Some genes (coding for CD36, α-TTP, α-tropomyosin, and collagenase) are affected by α-tocopherol at the transcriptional level. α-Tocopherol also induces inhibition of cell proliferation, platelet aggregation, and monocyte adhesion, which are thought to be due to direct interaction of α-tocopherol with cell components.[75,467] Properties independent of α-tocopherol have been ascribed to γ-tocopherol. These include the inhibition of cyclooxygenase activity, thus conferring antiinflammatory properties, and the natriuretic property of its main metabolite, γ-CEHC (2,7,8-trimethyl-2-(β-carboxyethyl)-6-hydroxychroman), not shared by α-CEHC.[286]

Requirements and Reference Nutrient Intakes

The requirement for vitamin E is related to the polyunsaturated fatty acid content of cellular structures and therefore depends on the nature and quantity of dietary fat that affect such composition. Hence the minimum adult requirement for vitamin E is not certain but is probably not more than 3 to 4 mg (4.5 to 6 IU) for RRR-α-tocopherol per day for those who ingest a diet containing the minimum of essential fatty acids (3% of calories).[172] Because vitamin E activity is derived from a series of tocopherols and tocotrienols in usual mixed diets, calculations based on their abundance and activity relative to the biologically most active RRR-α-tocopherol are used. The milligrams of β-tocopherol are multiplied by 0.5, those of γ-tocopherol by 0.1, and those of α-tocotrienol by 0.3. Their sum plus milligrams of α-tocopherol accounts for the milligrams of α-tocopherol equivalents. It has been estimated that a range of 7 to 13 mg of α-tocopherol equivalents (10 to 20 IU) can be expected in balanced diets supplying 1800 to 3000 kcal. This intake will maintain plasma concentrations of total tocopherols within the reference interval of 0.5 to 1.2 mg/dL, which also ensures an adequate concentration in all tissue.[53] Some investigators claim that the ratio of circulating α-tocopherol to total lipids (or triglycerides or β-lipoproteins) is a more accurate indicator of tissue vitamin E status than circulating α-tocopherol alone.

RDA for vitamin E was increased in the year 2000 by 50% from 10 to 15 mg/day for adults by the U.S. Food and Nutrition Board.[172] Most European reference intakes are related to the polyunsaturated fatty acid intake.[117] The changes in the United States were accompanied by some debate, critics arguing that this amount could not be met by the usual North American diet.[256,576] For infants up to 6 months, an AI of 4 mg/day was proposed, for infants 7 to 12 months an AI of 5 mg/day and the RDA for children 1 to 18 years was set at 6 to 15 mg/day, dependent upon age.[172] Another departure in the newer recommendations was that the daily requirement be met by RRR-α-tocopherol alone as the other forms of vitamin E are not converted to α-tocopherol and are poorly recognized by the α-tocopherol transfer protein in the liver.

Intravenous Supply

The recommended amount of vitamin E to be supplied intravenously to adults is 10 mg as α-tocopherol.[243] This is rather lower than the oral provision, but takes into account the fact that it is completely delivered into the blood stream.

Deficiency

Premature and low birth weight infants are particularly susceptible to development of vitamin E deficiency, because placental transfer is poor and infants have such limited adipose tissue where much of the vitamin is normally stored.[53] Signs of deficiency include irritability, edema, and hemolytic anemia. The anemia reflects the shortened life span of erythrocytes with fragile membranes; it does not respond to iron therapy, which may aggravate the condition. Although symptoms of vitamin E deficiency are rare in children and adults, deficiency can occur in some conditions. Fat malabsorption states, such as cystic fibrosis and chronic cholestasis in children, can cause neuropathy[537] and hemolytic anemia[621] as can the genetic disorder abetalipoproteinemia (within which vitamin E is transported).[404] Mutations of the gene coding for α-TTP lead to very low plasma α-tocopherol concentrations and cause neurological symptoms, including cerebellar ataxia.[506] Plasma concentrations may only be normalized by administering large amounts (up to 2 g/day) of vitamin E.

Toxicity

Excess vitamin E intake is usually only achieved by dietary supplementation. Such supplementation is contraindicated in subjects with coagulation defects caused by vitamin K deficiency or those receiving anticoagulant drugs. The U.S. Food and Nutrition Board has recommended a tolerable upper limit of 1000 mg/day of vitamin E for adults of 19 years and older, based on the absence of hemorrhagic toxicity in animal models,[172] though this has been challenged on the grounds that in those regularly taking aspirin this intake may be associated with an increased risk of bleeding.[256] A

1992 comprehensive review of tolerance and safety of vitamin E suggested that intakes of up to 3000 mg/day were safe; reversible side effects of gastrointestinal symptoms, increased creatinuria, and impairment of blood coagulation are seen at intakes of 1000 to 3000 mg/day.[298] However, as noted above, long term use of intakes of more than 400 mg per day may cause increased mortality.

Laboratory Assessment of Status

Assessment of vitamin E status has been achieved by functional methods, such as protection of erythrocyte hemolysis on addition of peroxide[151] or the inhibition of lipid peroxidation products (malondialdehyde, thiobarbituric acid-reactive substances, ethane, or pentane)[591] or by direct measurement of vitamin E concentration in tissue (erythrocytes, lymphocytes, or platelets) or serum. Early direct methods used photometric or fluorometric measurement often based on the Emmerie-Engel procedure in which tocopherol is oxidized to tocopheryl quinone by $FeCl_3$ and the resultant Fe^{2+} coupled with α,α'-dipyridyl to form a red color. Later, chromatographic methods were used, including thin layer and gas liquid, which had the ability to separate the tocopherols and tocotrienols, but these were labor intensive and time consuming. HPLC is presently the method of choice for quantitation of tocopherols in serum as it has the advantage of accuracy (by the use of primary standards) and reproducibility (between-batch coefficients of variation of 7% or better) and the ability to quantitate multiple analytes, including vitamin A and some carotenoids, in a single analytical run.[573,634] Both α- and γ-tocopherols are the principal vitamers seen, though others may be detected with minor modifications to the analytical conditions.

Reference Intervals

Guidance reference intervals for serum or plasma (heparin) vitamin E are 0.1 to 0.5 mg/dL (2.3 to 11.6 μmol/L) for premature neonates[20]; 0.3 to 0.9 mg/dL (7 to 21 μmol/L) for children (1 to 12 years)[339]; 0.6 to 1.0 mg/dL (14 to 23 μmol/L) for adolescents (13 to 19 years); and 0.5 to 1.8 mg/dL (12 to 42 μmol/L) for adults.[595]

VITAMIN K

Vitamin K promotes clotting of the blood and is required for the conversion of several clotting factors and prothrombin, and is of growing interest in bone metabolism.

Chemistry

Compounds in the vitamin K series are 2-methyl-1,4-napthoquinones, which are substituted with side chains at carbon 3. *Phylloquinone* (K_1 type) synthesized in plants and the *menaquinones* (K_2 type) of bacterial origin are the two principal natural classes of vitamin K (Figure 30-6). The principal vitamin K_1 (phylloquinone) bears a saturated, phytol, 20-carbon side chain derived from 4 isoprenoid units; this is the main K vitamin produced by plants and is the major dietary form for humans.[517] K_2 shows greater variation, but an all-*trans*-farnesylgeranylgeranyl, 35-carbon chain of 7 isoprenoid units is typical; these are produced in humans by the large bowel bacterial mass, though their contribution to vitamin K status remains a matter of dispute. Several synthetic analogues and derivatives have been used in human nutrition; most relate to or derive from *menadione* (K_3), which lacks a side-chain substituent at position 3, but which can be converted to menaquinone (MK) (e.g., MK-4, where 4 is the number of isoprenoid side chains) by addition of the side chain in the liver. The K vitamins are insoluble in water but dissolve in organic fat solvents. They are destroyed by alkaline solutions and reducing agents and are also sensitive to ultraviolet light.

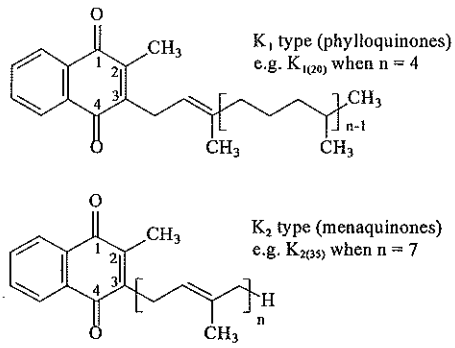

Figure 30-6 Vitaminic forms of vitamin K.

Dietary Sources

The main dietary sources of the phylloquinones are green vegetables, margarines, and plant oils, whereas some menaquinones are obtained from cheese, other milk products, and eggs.[509]

Absorption, Transport, Metabolism, and Excretion

The absorption of natural vitamin K from the small intestine into the lymphatic system is facilitated by bile, as is true for other fat-soluble materials.[66,160] Efficiency of absorption varies from 15% to 65% as reflected by recovery in lymph within 24 hours. Vitamins K_1 and K_2 are bound to chylomicrons for transport from mucosal cells to the liver. Menadione (K_3) is more rapidly and completely absorbed from the gut before entering the portal blood. In liver, intracellular distribution is mostly in the microsomal fraction, where phenylation of menadione to form K_2 occurs. Release of vitamin K to the blood stream allows association with circulating β-lipoproteins for transport to other tissue. Significant levels of vitamin K have been noted in the spleen and skeletal muscle.

Within metabolically active and vitamin K–using tissue, especially liver, a microsomal vitamin K cycle exists (Figure 30-7).[237] The vitamin (quinone) is normally reduced by a thiol-sensitive flavoprotein system to the hydroquinone, which then can couple to the oxygen- and carbon dioxide–using γ-carboxylation of glutamyl residues in specific pro-

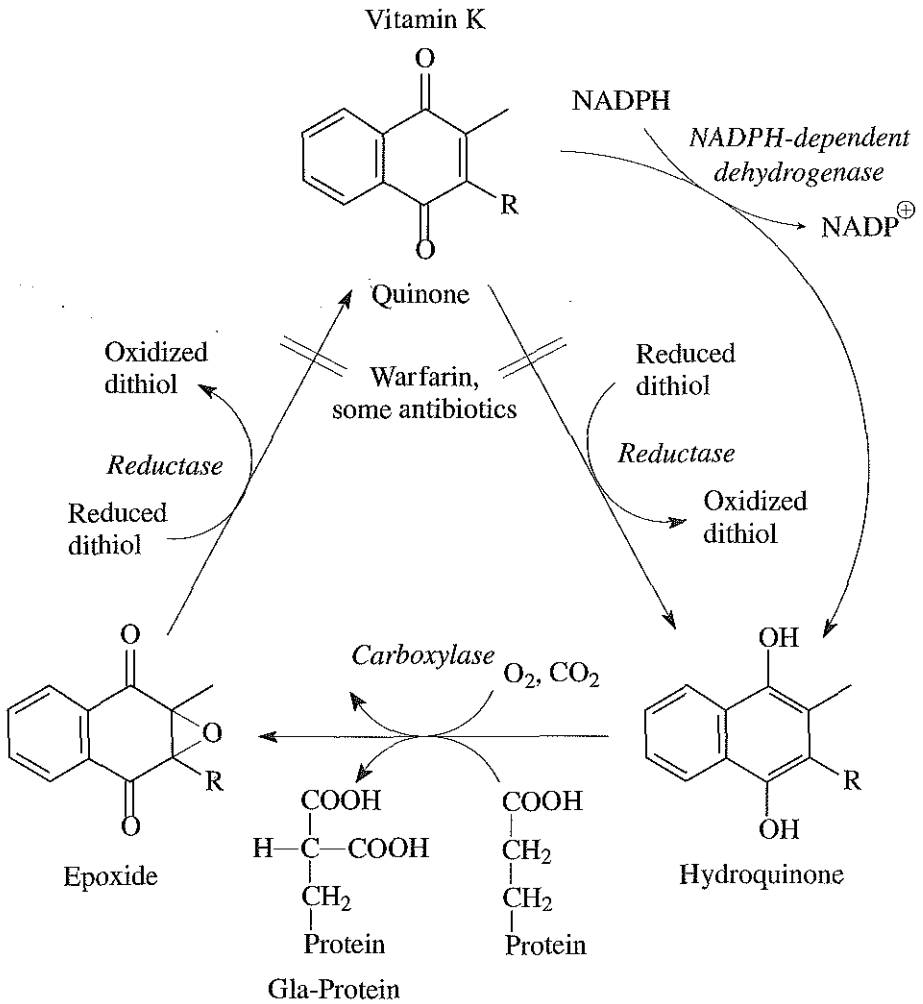

Figure 30-7 Metabolic cycling of vitamin K, the effect of warfarin, and the formation of Gla proteins.

teins (e.g., prothrombin).[160] The 2,3-epoxide of vitamin K that is subsequently formed is reduced to the starting vitamin K quinones, a process that can be antagonized by such vitamin K antagonists as warfarin.

Only traces of urinary metabolites of vitamins K_1 and K_2 appear in urine a considerable portion of vitamin K_3 (menadione) is conjugated at the hydroquinone level to form β-glucuronide and sulfate esters, which are excreted.

Functions

The essential and most thoroughly defined role of vitamin K is as a cofactor to vitamin K–dependent carboxylase, an enzyme necessary for the posttranslational conversion of specific glutamyl residues in target proteins to γ-carboxyglutamyl (Gla) residues. This γ-carboxylation increases the affinity of these proteins for calcium.[48] The antihemorrhagic function of vitamin K depends upon the formation of the Gla proteins prothrombin (factor II), proconvertin (factor VII), plasma thromboplastin component (factor IX), and Stuart factor (factor X), which together with two other hemostatic vitamin K–dependent proteins, proteins C and S and Ca^{2+}, initiate a process to form thrombin that then catalyzes the conversion of fibrinogen to a fibrin clot.[413]

Proteins that contain γ-carboxyglutamyl are also abundant in bone tissue, with osteocalcin accounting for up to 80% of the total γ-carboxyglutamyl content of mature bone. Many epidemiological studies, such as the 1999 Nurses' Health Study[161] and a 2000 study,[62] have shown an association between low vitamin K intakes and hip fracture risk, but not bone mineral density (BMD) measurements. Intervention studies have shown that vitamin K can increase BMD in osteoporotic subjects and reduce fracture rates,[531] though these studies have used menaquinone-4 in pharmacological rather than physiological doses. The improvement in bone markers was accompanied by a significant fall in the concentration of undercarboxylated osteocalcin in the treated groups. There is also evidence that vitamins K and D may act synergistically in maintaining bone density.[273]

A further major Gla protein, matrix Gla protein (MGP)—containing 5 residues of γ-carboxyglutamic acid—is found in vascular smooth muscle, bone, and many soft tissues (heart, kidney, and lungs). It is thought that MGP accumulates at sites of calcification, including calcified aortic

valves and bone, and is a potent inhibitor of calcification. In experimental studies with mice lacking the gene coding for MGP, calcification of the arteries was observed that led to hemorrhagic death of the animals as a result of blood vessel rupture.[352] Results from studies such as these have led to suggestions that vitamin K could play a role in vascular disease, though as yet clinical evidence is sparse.

Requirements and Reference Nutrient Intakes

Although the human gut bacteria synthesize large amounts of menaquinones, and such compounds are found in the liver in concentrations up to 10 times those of phylloquinones, the absorption of these compounds has been difficult to demonstrate and dietary restriction of vitamin K does lead to evidence of inadequacy, as demonstrated by undercarboxylation of vitamin K–dependent proteins.[160] Thus dietary reference intakes for vitamin K have recently been revised by the Food and Nutrition Board of the U.S. Institute of Medicine. Current recommendations are 120 μg/day for men over 18 years; 90 μg/day for women older than 18 years, including those pregnant or lactating; 30 to 75 μg/day for children 1 to 18 years, dependent upon age; 2.0 μg/day for infants up to 6 months; and 2.5 μg/day for infants between 7 and 12 months, the latter requirements being met by mature breast milk.[174] The dietary intake of phylloquinone in North American and most European populations studied has been estimated at around 150 μg/day for subjects over 55 years and around 80 μg/day for younger subjects, though intakes in the Netherlands have been reported to be 2 to 3 times higher than these estimates.[509]

Intravenous Supply

In the United States, whether vitamin K should be included in preparations of vitamins for use in TPN is controversial. Although this has been standard in Europe for many years,[522] the long-standing recommendation from the American Medical Association was not to include vitamin K, since this would complicate the provision of adequate warfarin therapy in those patients who require anticoagulation.[9] However, 2003 requirements of the Food and Drug Administration (FDA) have specified that vitamin K should be included in vitamin supplements for both infants and adults, making the judgment that the physiological and practical benefits of regular provision outweigh any problems in readjusting warfarin dosage.[243] The adult recommended intravenous (IV) dose is 150 μg/day, which is provided as phytonadione.

Deficiency

Although vitamin K deficiency in the adult is uncommon, the risk is increased for fat malabsorption states (bile duct obstruction, cystic fibrosis, and chronic pancreatitis) and liver disease.[314] Risk is also increased by the use of drugs that interfere with vitamin K metabolism, such as the coumarin anticoagulants (e.g., warfarin) and antibiotics containing the *N*-methylthiotetrazole side chain (e.g., cephalosporin).[516] Other at-risk groups are hospitalized patients with poor nutrient intakes or those receiving TPN, when fat-soluble vitamin supplements may not fully meet requirements. Conversely, ingestion of supraphysiological doses of vitamins A and E has also been reported to induce vitamin K deficiency, probably by competitive mechanisms.[432] Defective blood coagulation and demonstration of abnormal noncarboxylated prothrombin are at present the only well-established signs of vitamin K deficiency.

Hemorrhagic disease of the newborn can develop readily because of (1) poor placental transfer of vitamin K, (2) hepatic immaturity leading to inadequate synthesis of coagulation proteins, and (3) the low vitamin K content of early breast milk. Prothrombin levels during this period are only about 25% of the adult levels. Severe diarrhea and antibiotics used to suppress diarrhea readily exacerbate the situation, so prothrombin levels can drop below 5% of the adult level and bleeding can occur. This condition is routinely prevented by the prophylactic administration of 0.5 to 1.0 mg of phylloquinone intramuscularly, or 2.0 mg given orally immediately after birth.

Toxicity

The use of high doses of naturally occurring vitamin K (K_1 and K_2) appears to have no untoward effect; however, menadione (K_3) treatment can lead to the formation of erythrocyte cytoplasmic inclusions known as Heinz bodies and hemolytic anemia.[406] With severe hemolysis, increased bilirubin formation and undeveloped capacity for its conjugation may produce kernicterus in the newborn.

As no adverse effects associated with vitamin K consumption from food or supplements have been reported in humans or animals, the U.S. Institute of Medicine has reported that a quantitative risk assessment cannot be performed, and thus a UL cannot be derived for vitamin K.[174]

Laboratory Assessment of Status

Because of its relatively low plasma concentration (approximately 50 times lower than vitamin D and at least 10^3 times lower than vitamins A or E), vitamin K has long presented an analytical challenge. For this reason, vitamin K status has traditionally been assessed by functional methods, primarily by its effect on clotting time. The "prothrombin time" (PT) is assessed by adding to recalcified plasma a portion of tissue thromboplastin and measuring the clotting time against a normal control sample. In vitamin K deficiency, the PT may rise above 30 seconds (normal: 10 to 14 seconds), and at least 2 seconds beyond the control time. Attempts at cross-laboratory standardization have led to the introduction of the Internationalized Normal Ratio (INR), where the PT is expressed as a fraction of the control time. A more sensitive (1000-fold) assessment of vitamin K status with respect to prothrombin can be made by the immunoassay of des-γ-carboxy prothrombin, or undercarboxylated prothrombin, PIVKA-II (protein induced by vitamin K absence or antagonism).[58] Concentrations of PIVKA-II of greater than

2 ng/mL have been considered to indicate vitamin K deficiency.[314] A newer measurement of deficient γ-carboxylation, plasma undercarboxylated osteocalcin, was developed in 1995[539] and has been shown to correlate individually with PIVKA-II and plasma phylloquinone concentrations and has a better correlation with plasma phylloquinone than PIVKA-II.[540] In this 1995 study of biochemical indices of vitamin K nutritional status in a healthy adult population, and a later one looking at changes in response to dietary phylloquinone,[538] the urinary γ-carboxyglutamic acid/creatinine ratio was measured by derivatization, HPLC separation, and fluorometric detection[229] and also shown to be sensitive to changes in dietary phylloquinone intake. This marker may have advantages in epidemiological surveys as a less invasive sample.

The direct measurement of plasma phylloquinone is probably the best indicator of vitamin K status and has been shown to correlate well with intake.[538] HPLC methods have been reviewed,[515] and typically require 0.5 to 2.0 mL of serum or plasma. Protein precipitation and lipid extraction (often into hexane), followed by solvent evaporation; preparative HPLC (to isolate vitamin K from other lipids); reevaporation of the vitamin K–rich fraction; dilution in the mobile phase; and further HPLC, with either electrochemical or fluorometric detection[281] often after postcolumn reduction, are required. Typical between-batch imprecision values are coefficient of variation (CV)s of 11% to 18% with limits of detection of lower than 50 pmol/L. An external quality assessment scheme (EQAS) is available in the UK.

Reference Interval

A guidance reference interval for plasma vitamin K is 0.13 to 1.19 ng/mL (0.29 to 2.64 nmol/L).[574]

Vitamin B_1—Thiamine

Thiamine, also known as vitamin B_1, forms the coenzyme thiamine pyrophosphate (TPP). It is required for the essential decarboxylation reactions catalyzed by the pyruvate and 2-oxoglutarate complexes.

Chemistry

The structure of *thiamine* (vitamin B_1) (3-[4-amino-2-methyl-pyrimidyl-5-methyl]-4-methyl-5-[β-hydroxyethyl]thiazole) is that of a pyrimidine ring, bearing an amino group, linked by a methylene bridge to a thiazole ring (Figure 30-8). The thiazole has a primary alcohol side chain at C5, which can be phosphorylated in vivo to produce thiamine phosphate esters, the most common of which is thiamine pyrophosphate (TPP) (also known as thiamine diphosphate, cocarboxylase). Monophosphate and triphosphate esters also occur. The basic vitamin is isolated or synthesized and handled as a solid thiazolium salt (e.g., thiamine chloride hydrochloride). Thiamine is somewhat heat labile, particularly in alkaline solutions, where base attack occurs at C2 of the thiazolium ring.

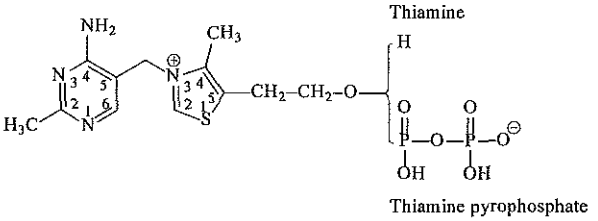

Figure 30-8 Thiamine and the pyrophosphate coenzyme.

Dietary Sources

Small amounts of thiamine and its phosphates are present in most plant and animal tissue, but more abundant sources are unrefined cereal grains, liver, heart, kidney, and lean cuts of pork. The enrichment of flour and derived food products, particularly breakfast cereals, has considerably increased the availability of this vitamin.

Absorption, Transport, Metabolism, and Excretion

Thiamine absorption occurs primarily in the proximal small intestine[317] by both a saturable (thiamine transporter) process at low concentration (1 μmol/L, or lower) and by simple passive diffusion beyond that, though percentage absorption diminishes with increased dose. The absorbed thiamine undergoes intracellular phosphorylation, mainly to the pyrophosphate, but at the serosal side 90% of the transferred thiamine is in the free form.[469] Thiamine uptake is enhanced by thiamine deficiency and reduced by thyroid hormone, diabetes, and ethanol ingestion. The gene for the specific thiamine transporter has been identified, and the transporter cloned.[166] Thiamine is carried by the portal blood to the liver. The free vitamin occurs in the plasma, but the coenzyme, TPP, is the primary cellular component. Approximately 30 mg is stored in the body with 80% as the pyrophosphate, 10% as triphosphate, and the rest as thiamine and its monophosphate. About half of the body stores are found in skeletal muscles, with much of the remainder in heart, liver, kidneys, and nervous tissues (including the brain, which contains most of the triphosphate).

The three tissue enzymes known to participate in formation of the phosphate esters are (1) thiaminokinase (a pyrophosphokinase), which catalyzes formation of TPP and adenosine monophosphate (AMP) from thiamine and adenosine triphosphate (ATP); (2) TPP-ATP phosphoryltransferase (cytosolic 5′-adenylic kinase),[297] which forms the triphosphate and adenosine diphosphate from TPP and ATP; and (3) thiamine triphosphatase, which hydrolyzes TPP to the monophosphate. Although thiaminokinase is widespread, the phosphoryl transferase and membrane-associated triphosphatase are mainly in nervous tissue.

Using radio-labeled thiamine probes, a study of thiamine metabolism at normal loads produced an estimated half-life of thiamine of 9.5 to 18.5 days, and showed a large number of breakdown products in the urine.[17] Several of these urinary catabolites are shown in Figure 30-9.

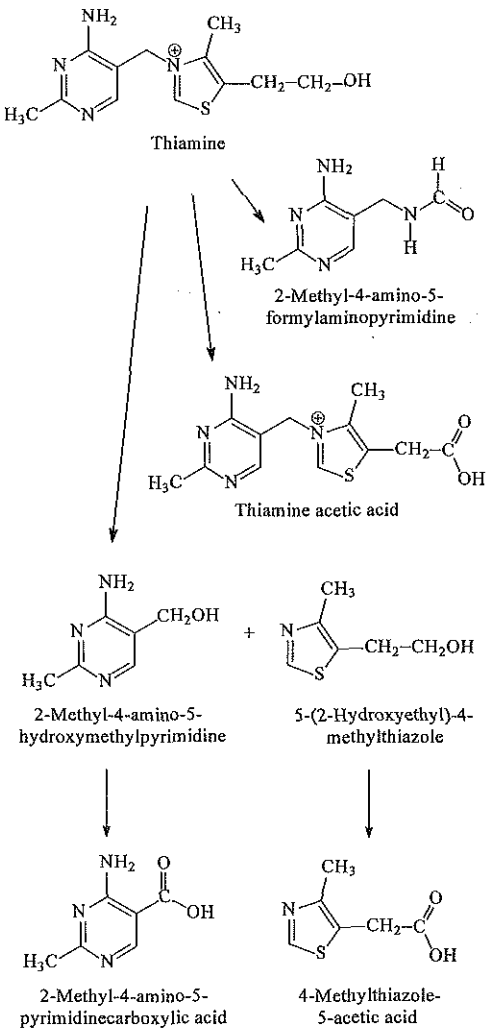

Figure 30-9 Principal urinary catabolites of thiamine.

Functions

Thiamine is required by the body as the pyrophosphate (TPP) in two general types of reaction, the oxidative decarboxylation of α-keto acids catalyzed by dehydrogenase complexes and the formation of α-ketols (ketoses) as catalyzed by transketolase, and as the triphosphate (TTP) within the nervous system. TPP functions as the Mg^{2+}-coordinated coenzyme for so-called "active aldehyde" transfers in multienzyme dehydrogenase complexes that affect decarboxylative conversion of α-keto (2-oxo) acids to acyl-coenzyme A (acyl-CoA) derivatives, such as pyruvate dehydrogenase and α-ketoglutarate dehydrogenase. These are often localized in the mitochondria, where efficient use in the Krebs tricarboxylic acid (citric acid) cycle follows.

Three types of subunit proteins constitute such dehydrogenase complexes: (1) a TPP-dependent decarboxylase, which converts the α-keto acid to an α-hydroxyalkyl-TPP complex; (2) a transacylase core, which contains lipoyl residues that are acylated by the α-hydroxyalkyl-TPP; and (3) a flavin adenine dinucleotide (FAD)–dependent dihydrolipoyl dehydrogenase, which reoxidizes the reduced lipoyl residues produced after transfer of their acyl functions to reduced CoA. In addition to energy and an ultimate ATP supply derived from reactions in the Krebs cycle, the initial pyruvate dehydrogenase–catalyzed step provides acetyl-CoA as a biosynthetic precursor to other essential compounds, such as lipids and acetylcholine of the parasympathetic nervous system.

Transketolase is a TPP-dependent enzyme found in the cytosol of many tissues, especially liver and blood cells, in which principal carbohydrate pathways exist. In the pentose phosphate pathway, which additionally supplies reduced nicotinamide-adenine dinucleotide phosphate (NADPH) necessary for biosynthetic reactions, this enzyme catalyzes the reversible transfer of a glycoaldehyde moiety from the first two carbons of a donor ketose phosphate to the aldehyde carbon of an aldose phosphate.

Although thiamine as its pyrophosphate contributes to nervous system composition and function in such essential reactions as energy production and biosynthesis of lipids and acetylcholine, a further specific, noncofactor role for thiamine has been proposed in excitable cells. Here, TTP is thought to be involved in the regulation of ion channels, specifically chloride channels of large unitary conductance, the so called maxi-Cl channels.[50] TTP may also act as a phosphate donor for the phosphorylation of proteins, suggesting a potential role in cell signaling.[356] A subacute necrotizing encephalomyelopathy is seen in patients with Leigh syndrome, resulting from the presence of an inhibitor of TPP-ATP phosphoryl transferase,[559] and consequent reduction in TTP concentration.

Requirements and Reference Nutrient Intakes

Because thiamine is necessary mainly for the metabolism of carbohydrates, fats, and alcohol, there is a direct correlation of need with the amount of metabolizable food intake. There is a greater requirement under situations in which metabolism is increased (e.g., in the normal conditions of increased muscular activity, pregnancy, and lactation, or in the abnormal cases of protracted fever, posttrauma, and hyperthyroidism.)[559] Clinical signs of deficiency in adults can be prevented with intakes of thiamine above 0.15 to 0.2 mg/1000 kcal, but 0.35 to 0.4 mg/1000 kcal may be closer to a level necessary to maintain urinary excretion and TPP-dependent erythrocyte transketolase activity within normal reference intervals.[170] With further considerations of average caloric intakes and activities in different age groups, the most recent recommendations of RDA, expressed as mg/day, are 1.2 mg/day for males 19 years and older and 1.1 mg/day for females 19 years and older.[170] The requirement for pregnant women increases early in pregnancy and then remains constant; an additional allowance of 0.3 mg/day is recommended. The lactating woman secretes 0.1 to 0.2 mg of thiamine per day in milk, so an additional 0.3-mg/day allowance is suggested. Based on the thiamine content of human milk and with an increment considered to provide a margin of safety, 0.2 mg/day is the allowance

for infants up to 6 months, and 0.3 mg/day for infants 7 to 12 months. Increases above this are suggested for growing children.

Intravenous Supply

Traditionally the intravenous recommendation was for 3 mg/day for adults, usually provided as thiamine hydrochloride, but also as thiamine mononitrate or tetrahydrate. In the 2000 FDA recommendations, this has been increased to 6 mg/day,[243] recognizing the likelihood of increased demands for thiamine caused by the hypercatabolism in such patients, and the very serious potential complications of deficiency.[599]

Deficiency

The causes of thiamine deficiency[66] include inadequate intake caused by diets largely dependent on milled, nonenriched grains, such as rice and wheat, or by the ingestion of raw fish containing microbial thiaminases,[148] which hydrolytically destroy the vitamin in the gastrointestinal tract. Tea may contain antithiamine factors that have been detected in certain other plant extracts. Chronic alcoholism often leads to thiamine deficiency caused by reduced intake, impaired absorption, impaired use, and reduced storage[570] and may lead clinically to the Wernicke-Korsakoff syndrome. Other at-risk groups include those receiving parenteral nutrition without adequate thiamine supplementation,[408,476] elderly patients taking diuretics,[551] and patients undergoing long-term renal dialysis.[259]

Beriberi is the disease resulting from thiamine deficiency. Clinical signs of thiamine deficiency primarily involve the nervous and cardiovascular systems.[558,559] In the adult, symptoms most frequently observed are mental confusion, anorexia, muscular weakness, ataxia, peripheral paralysis, ophthalmoplegia, edema (wet beriberi), muscle wasting (dry beriberi), tachycardia, and an enlarged heart. In infants, symptoms appear suddenly and severely, often involving cardiac failure and cyanosis. Commonly the distinction between wet (cardiovascular) and dry (neuritic) manifestations of beriberi relates to duration and severity of the deficiency, the degree of physical exertion, and caloric intake.[622] The wet or edematous condition results from severe physical exertion and high carbohydrate intake, whereas the dry or polyneuritic form stems from relative inactivity with caloric restriction during the chronic deficiency. The three major physiological derangements that typically involve the cardiovascular system are peripheral vasodilatation leading to a high-output state, biventricular myocardial failure, and retention of sodium and water, leading to edema. Nervous system involvement includes peripheral neuropathy, Wernicke's encephalopathy, and the amnesic psychosis of Korsakoff's syndrome. More rarely, but especially in seriously ill patients in hospitals, an acute form of cardiac failure has been described (Shoshin beri-beri), which may be fatal, but is successfully and rapidly reversed with high-dose intravenous thiamine.[599]

There are several thiamine-responsive disorders caused by genetic mutation. In thiamine-responsive megaloblastic anemia (TRMA), the gene has been mapped and cloned and designated "SLC19A2" as a member of the solute carrier gene super family. Mutations of this gene, the product of which is a membrane protein that transports thiamine with submicromolar affinity, have been found in all TRMA kindreds studied.[416,459] Thiamine-responsive pyruvate dehydrogenase complex deficiency, presenting with lactic acidosis, can be caused by a point mutation within the thiamine pyrophosphate-binding region,[407] and a thiamine-responsive branched-chain keto acid dehydrogenase complex deficiency, presenting as a form of maple syrup urine disease, is caused by mutations in the E1 alpha subunit of the enzyme complex.[628] Therapeutic doses of 5 to 20 mg of thiamine daily have proved beneficial in these cases.

Toxicity

As there are no reports of adverse effects from consumption of excess thiamine from food and supplements (supplements of 50 mg/day are widely available without prescription), and the data are inadequate for a quantitative risk assessment, no UL has been defined for thiamine.[170] However, as stimulators of transketolase enzyme synthesis such as thiamine support a high rate of nucleic acid ribose synthesis necessary for tumor cell survival, chemotherapy resistance, and proliferation, some concern has been expressed that thiamine supplementation of common food products may contribute to increased cancer rates in the Western world.[64] There is, however, little evidence to support this assumption. Rarely, individuals given high-dose intravenous thiamine in treatment of beriberi have developed anaphylaxis, the frequency being about 1:100,000.

Laboratory Assessment of Status

As a thiamine deficiency develops, there is a rather rapid loss of the vitamin from all tissue except the brain. The decrease of TPP in the erythrocyte roughly parallels the decrease of this coenzyme in other tissue. During this time, thiamine levels in urine fall to near zero; the urinary metabolites remain high for some time before decreasing.

Historically, assessment of thiamine status was by animal bioassay (the correction of bradycardia in thiamine-deficient rats) and later by microbiological assays using the fungus *Phycomyces blakesleeanus*, yeast fermentation, or bacteria of the *Staphylococcus, Streptococcus,* or *Lactobacillus* species. Some bacterial microbiological assays are still in use in the food industry. Early chemical methods were often based upon the production of a fluorophore, thiochrome, when thiamine is oxidized with ferricyanide in alkaline solution, a property that is used in some modern chromatographic methods.

Because the basic biological function of thiamine is to act as the pyrophosphate cofactor in a number of enzyme systems, two differing approaches to assessment of status became available. The analyte, either free or phosphorylated, can be measured directly in a suitable body fluid or tissue or its properties as an enzymatic cofactor can be exploited in a functional assay. Both approaches have their advantages and

disadvantages, and a consensus as to which is the more useful has not been achieved; the two are probably complementary, each supplying some, but not all, of the information necessary to assess thiamine adequacy (Table 30-3).

The most commonly used enzyme for the functional assay is transketolase. Transketolase catalyzes two reactions in the pentose phosphate pathway (Figure 30-10). As an enzyme within the erythrocyte, transketolase is independent of nonspecific changes in the extracellular plasma. As vitamin B_1 deficiency becomes more severe, (1) thiamine becomes limiting in the body cells, (2) the amount of the coenzyme is depleted, and (3) the transketolase activity subsequently diminishes. The "TPP effect" measures the extent of depletion of the transketolase enzyme for coenzyme by assaying enzyme activity before and after TPP supplementation. The percent increase in activity is defined as the TPP effect or activation coefficient. Several methods are available to measure transketolase activity. In the Brin procedure,[77] activities of holo forms and apo forms of transketolase in erythrocyte hemolysates are measured before and after addition of TPP, by photometric determinations of the amount of ribose-5′-phosphate used or hexose-6-phosphate formed. This method is reliable but time consuming. In an alternative method, the rate of formation of glyceraldehyde-3-P is measured indirectly by a coupled reaction in a system containing excess triosephosphate isomerase (TIM), glycerolphosphate dehydrogenase (GD), and NADH.[536] Glyceraldehyde-3-P is converted by TIM to dihydroxyacetone-P, which in the presence of GD and NADH is reduced to glycerol-1-P. The rate of NADH oxidation, measured at 340 nm, is proportional to the transketolase activity. Kinetic methods such as these have been automated with consequent improvements in throughput and precision.[401]

TABLE 30-3 Relative Merits of Direct (Erythrocyte Thiamine Pyrophosphate) or Functional (Erythrocyte Transketolase) Measurements in Assessing Thiamine Status

Erythrocyte Thiamine Pyrophosphate	Erythrocyte Transketolase Activation
Advantages	**Advantages**
• Pure standard available • Precise and robust methodology • More stable when frozen • Depletes at rate similar to other organs • Methodology (HPLC) allows measurement of other forms of thiamine • Can detect tissue accumulation	• May correlate better with clinical conditions in repleted patients • Large database established
Disadvantages	**Disadvantages**
May normalize very early with parenteral treatment	• Depletion of apoenzyme may be nonnutritional (e.g., liver disease, diabetes) • Variants may have abnormal binding • May be influenced by cofactor deficiencies (e.g., magnesium) • Difficult to standardize, less robust • Derived activation coefficient reduces precision

The transketolase activation test is in reality two tests: one a measurement of basal activity and the other the degree to which the basal activity can be increased by exogenous thiamine pyrophosphate, and each may be influenced by different factors. There is evidence that chronic deficiency states of thiamine may down regulate synthesis of the apoenzyme.[473] In comparison studies against erythrocyte TPP concentrations, better correlations were obtained with basal activity rather than the activation coefficient.[24]

Other potential disadvantages of the transketolase test are reductions in apoenzyme synthesis in diseases other than thiamine deficiency (diabetes,[181] liver disease[156]), reduced apoenzyme to coenzyme binding with apotransketolase variants,[289] lack of stability relative to TPP on processing and storage,[453] lack of a standard or EQAS, and variations in published upper limits for the activation coefficient from 15.5% to 40%. The main advantages of the transketolase test are that it is widely used, has a relatively large database and body of experience, and is claimed to correlate better with clinical conditions in alcoholic patients being repleted with thiamine.[258]

Direct measurement of circulating thiamine concentration may be made in plasma, erythrocytes, or whole blood. The plasma (or serum) concentration is thought to reflect recent intake and is mainly unphosphorylated thiamine at low concentration (around 10 to 20 nmol/L). Because the erythrocyte contains approximately 80% of the total thiamine content of whole blood,[503] mainly as the pyrophosphate,[304] and erythrocyte thiamine stores deplete at a similar rate to other major organs,[76] HPLC measurement of TPP in erythrocytes is a good indicator of body stores. Typical HPLC methods include a protein precipitation step, precolumn or postcolumn formation of the fluorophore; thiochrome, usually with alkaline ferricyanide; and isocratic separation.[23,555] The method is easily standardized with pure

thiamine pyrophosphate, has good precision (interbatch CVs of 5% to 8%), acceptable limits of detection (around 10 nmol/L), and the analyte is stable at −70 °C for at least 7 months and at room temperature for 48 hours.[24] Whole blood samples may be analyzed in a manner similar to washed erythrocytes and have the advantage of simpler sample handling, but are subject to variable plasma dilution. However, a good correlation has been obtained between erythrocyte and whole blood TPP concentrations, particularly when whole blood TPP included a correction for hemoglobin (Hb). At the time of writing, no EQAS are available for thiamine analysis.

Determination of the urinary excretion of thiamine in a 4-hour specimen, especially with comparison of excretion before and after a test load, is helpful in differentiating among extremes of thiamine status. However, as with most assessments based on amount of water-soluble vitamins in urine, excretion can be influenced considerably by dietary intake, absorption, and other factors. Measurements of certain urinary metabolites, notably thiamine acetic acid, have also been suggested as reflecting thiamine status.[412]

Reference Intervals

Reference intervals for thiamine and its esters depend upon whether (1) erythrocytes, whole blood, or plasma are used as a sample; (2) cellular concentrations are expressed per liter of packed red cells or grams of Hb; and (3) mass or SI units are used. Some guidance intervals are, for erythrocyte transketolase activity 0.75 to 1.30 U/g Hb (48.4 to 83.9 kU/mol Hb) and for percent TPP effect (activation), 0 to 15% is normal, 16% to 25% marginally deficient and >25% severely deficient with clinical signs. For direct TPP concentration measurements, typical intervals are 173 to 293 nmol/L erythrocytes and 90 to 140 nmol/L whole blood,[168] or 280 to 590 ng/g Hb in erythrocytes and 275 to 675 ng/g Hb in whole blood.[555]

Vitamin B_2—Riboflavin

Riboflavin, also known as vitamin B_2, is an essential component of FAD and flavin mononucleotide (FMN)—coenzymes that are involved in many redox reactions.

Chemistry

Vitamin B_2 refers to riboflavin and its related metabolites, which act as cofactors to several reduction-oxidation enzymes. The parent compound—riboflavin, 7,8-dimethyl-10-[1′-D-ribityl]isoalloxazine)—is a yellow fluorescent compound whose major physiological role is to act as a precursor for FMN (riboflavin-5′-phosphate) and FAD. FMN is formed from riboflavin by flavokinase-catalyzed phosphorylation, and FAD is formed from FMN and ATP by the action of FAD synthetase, also called pyrophosphorylase (Figure 30-11).[470] FAD is further converted by covalent bonding to form various tissue flavoproteins.[384] Flavins are stable during exposure to heat but are decomposed by light, which causes photodegradation of the D-ribitol side chain at position 10 of the isoalloxazine ring system to ultimately yield lumiflavin (7,8,10-trimethylisoalloxazine) under alkaline conditions and lumichrome (7,8-dimethylalloxazine) at all pH values, especially in neutral-to-acidic solutions. Flavins are chemically and biologically reduced to nearly colorless compounds that rapidly reoxidize on exposure to air (oxygen).

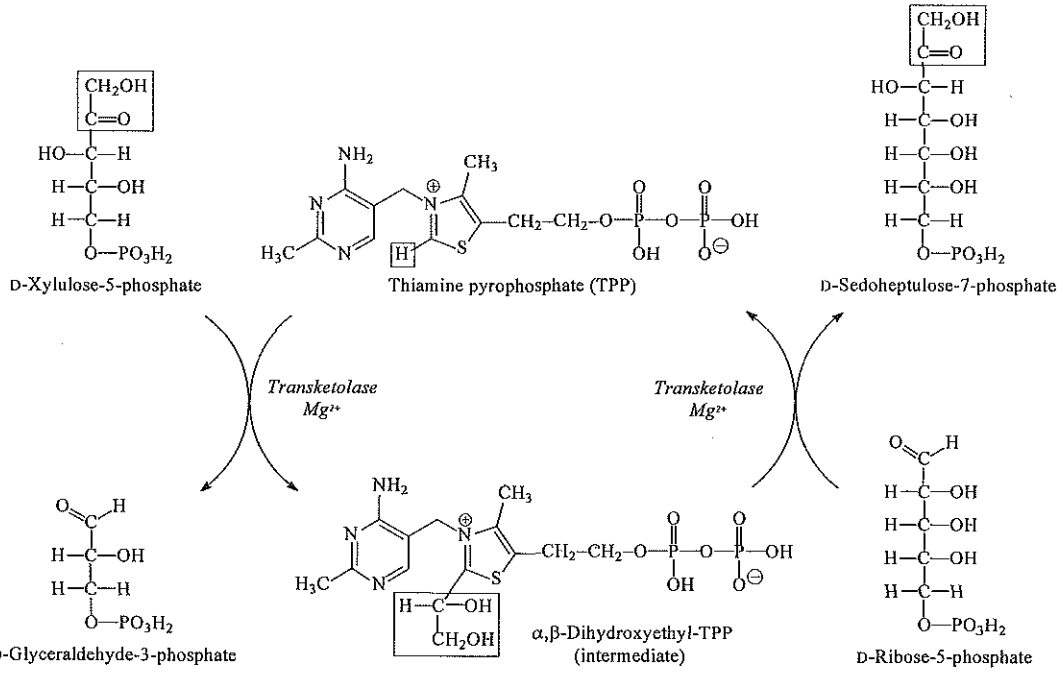

Figure 30-10 The transketolase reaction.

Dietary Sources

Rich sources of the coenzyme forms of the vitamin are liver, kidney, and heart. Many vegetables are also good sources, but cereals are rather low in flavin content. However, current practices of fortification and enrichment of cereal products have made these significant contributors to the daily requirement. Milk, from cows[480] and humans,[479] is a good source of the vitamin, but considerable loss can occur from exposure to light during pasteurization and bottling or as a result of irradiation to increase the vitamin D content.

Absorption, Transport, Metabolism, and Excretion

Most dietary riboflavin is taken in as a complex of food protein with the coenzymes FMN and FAD. These coenzymes are released from noncovalent attachment to proteins as a consequence of gastric acidification. Nonspecific action of pyrophosphatase and phosphatase on the coenzyme occurs in the upper gut.[370] The vitamin is primarily absorbed in the proximal small intestine by a saturable transport system that is rapid and proportional to intake before leveling off at doses near 27 mg riboflavin per day.[636] Bile salts appear to facilitate the uptake, and a modest amount of the vitamin circulates via the enterohepatic system.[470] Active transport at lower levels of intake was thought to be sodium ion–dependent and involve phosphorylation, though later work has suggested that uptake is independent of sodium ions.[488] The transport of flavins in human blood involves loose binding to albumin and tight binding to a number of globulins, with the major binding being to several classes of immunoglobulins (IgA, IgG, and IgM).[266,377] Pregnancy increases the concentration of carrier protein for riboflavin,[411] which results in a higher rate of riboflavin uptake at the maternal surface of the placenta.[123] The uptake of riboflavin into the cells of organs, such as liver, is facilitated, possibly requiring a specific carrier, at physiological concentrations, but can be by diffusion at higher concentrations.[67] Metabolic interconversions of flavins at the cellular level are outlined in Figure 30-12. Conversion of riboflavin to coenzymes occurs within the cellular cytoplasm of most tissue but particularly in the small intestine, liver, heart, and kidney. The obligatory first step is the ATP-dependent phosphorylation of the vitamin catalyzed by flavokinase. The FMN product can be complexed with specific apoenzymes to form several functional flavoproteins, but the larger quantity is further converted to FAD in a second ATP-dependent reaction catalyzed by FAD synthetase (pyrophosphorylase). Biosynthesis of flavocoenzymes, particularly at the flavokinase step, is probably tightly regulated. Thyroxine and triiodothyronine stimulate FMN and FAD synthesis in mammalian systems.[324] FAD is the predominant flavocoenzyme present in tissue where it is mainly complexed with numerous flavoprotein dehydrogenases and oxidases. Some FAD (less than 10%) can also become covalently linked to any of 5 specific amino acid residues of a few important apoenzymes.[142] Examples include the 8α-N(3)-histidyl FAD within succinate dehydrogenase and 8α-S-cysteinyl FAD within monoamine oxidase, both of mitochondrial localization. Turnover of covalently attached flavocoenzymes requires intracellular proteolysis, and further degradation of the coenzymes involves nonspecific pyrophosphatase cleavage of FAD to FMN and AMP, and further action by nonspecific phosphates on FMN and AMP. Because there is little storage of riboflavin as such, the urinary excretion reflects dietary intake. Milk contains reasonable quantities of the vitamin and lesser amounts of coenzyme, principally FMN. Smaller amounts of side-chain degradation products, such as lumichrome, 10-formylmethylflavin, and 10-(2′-hydroxyethyl)flavin, and ring-altered compounds are also excreted and may largely result from the action of intestinal

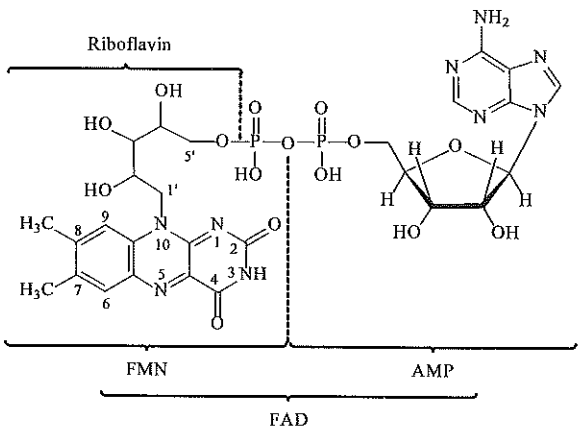

Figure 30-11 Riboflavin and FMN as components of FAD.

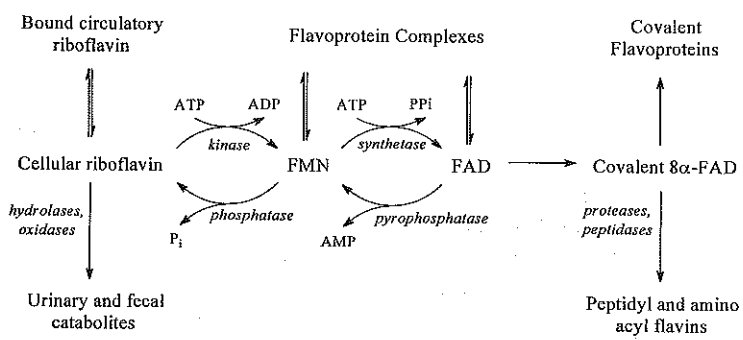

Figure 30-12 Cellular interconversions of flavins.

microorganisms.[104] Traces of 8α-flavin peptides and catabolites are found in urine and feces.

Functions

Riboflavin, as its coenzyme derivatives, is involved in a large variety of chemical reactions. These derivatives are capable of both one- and two-electron transfer processes, and play a pivotal role in coupling the two-electron oxidation of most organic substrates to the one-electron transfer of the respiratory chain,[364] thus being involved in energy production. They also function as electrophiles and nucleophiles, with covalent intermediates of flavin and substrate frequently being involved in catalysis. Flavoproteins catalyze dehydrogenation reactions, hydroxylations, oxidative decarboxylations, deoxygenations, and reductions of oxygen to hydrogen peroxide.[470] The chemical versatility of the flavoproteins is clearly controlled by specific interactions with the proteins with which they are bound.[364] Other major functions of riboflavin include drug metabolism in conjunction with the cytochrome P-450 enzymes and lipid metabolism.

Flavins also have both prooxidative and antioxidative functions. They are thought to contribute to oxidative stress through the ability to produce superoxide[364] and to catalyze the production of hydrogen peroxide. As an antioxidant, FAD is a coenzyme to glutathione reductase in the regeneration of reduced glutathione from oxidized glutathione, necessary for the removal of lipid peroxides. Riboflavin deficiency is associated with increased lipid peroxidation.[141] Flavins have also been linked with apoptosis[364] and have homocysteine-lowering properties, FAD being a cofactor to methylenetetrahydrofolate reductase in the remethylation of homocysteine.[394] Newer therapeutic uses of riboflavin are in the prophylaxis of migraine attacks[500] and in the treatment of lactic acidosis caused either by the use of nucleoside reverse transcriptase inhibitors in patients with the acquired immunodeficiency syndrome[179] or by genetic defects in the mitochondrial respiratory chain, such as in Leigh disease.[431]

Requirements and Reference Nutrient Intakes

Assessment of riboflavin status has been made on the basis of the relationship of dietary intake to overt signs of hyporiboflavinosis, urinary excretion of the vitamin, erythrocyte riboflavin content, and erythrocyte glutathione reductase activity.[170] Calculations have been based on protein allowances, energy intakes, and metabolic body size, but these do not differ significantly because they are interdependent. At least 0.5 mg of riboflavin per 1000 kcal is required by the adult, and 0.6 mg/1000 kcal constitutes the allowance suggested for all ages. Based on considerations such as these, the current RDA has been set at 1.3 mg/day for men of 19 to 70 years of age and older, and 1.1 mg/day for women in the same age group. Children 1 to 3 years old have an RDA of 0.5 mg/day, increasing to 0.6 mg/day up to age 8. From 8 to 18 years, RDAs progressively approach adult levels. Because pregnant women tend to excrete less riboflavin as pregnancy progresses and additionally exhibit FAD stimulation of erythrocyte glutathione reductase activity, recommended allowances call for an additional 0.3 mg/day during pregnancy. During lactation, between 18 and 80 μg of riboflavin are secreted daily into every 100 mL of human milk. Assuming that an infant will ingest an average of 750 mL of milk per day during its first 6 months and 600 mL/day for the next 6 months, this secretion rate translates into an ingestion of between 100 and 600 μg of riboflavin per day. Further assuming that 70% of maternally ingested riboflavin is used for milk production, these data suggest that the present RDA for lactating women should be increased by an additional 400 to 500 μg/day. Accordingly the RDA for lactating women has been set at 1.6 mg/day.[170]

Intravenous Supply

The recommended intravenous supply of riboflavin in adults is 3.6 mg/day.[9] Riboflavin in TPN mixtures may be subject to degradation under exposure to ultraviolet light, so bags containing riboflavin should either contain fat emulsion or be covered to provide protection from light.[519]

Deficiency

Although riboflavin has a wide distribution in foodstuffs, many people live for long periods on low intakes, and consequently, minor signs of deficiency are common in many parts of the world. In addition to poor intake, functional deficiency can be induced by diseases such as hypothyroidism and adrenal insufficiency that inhibit the conversion of riboflavin to its coenzyme derivatives and by drugs such as chlorpromazine, imipramine, and amitriptyline that have a similar tricyclic structure to riboflavin—the anticancer drug doxorubicin and the antimalarial quinacrine.[140,437] Excess ethanol ingestion interferes with both the digestion and absorption of riboflavin.[441]

Because flavin coenzymes are widely distributed in intermediary metabolism, the consequences of deficiency may be widespread. Because riboflavin coenzymes are involved in the metabolism of folic acid, pyridoxine, vitamin K, and niacin,[471] deficiency will affect enzyme systems other than those requiring flavin coenzymes. With increasing riboflavin deficiency, tissue concentrations of FMN and FAD fall, as does flavokinase activity, thus further decreasing FMN concentrations. FMN concentrations are decreased proportionally more than FAD concentrations. Decreases in the activities of enzymes requiring FMN generally follow the fall in tissue concentrations, whereas the FAD-dependent enzymes are more variably affected.[83]

The deficiency syndrome is characterized by sore throat, hyperemia, edema of the pharyngeal and oral mucous membranes, cheilosis, angular stomatitis, glossitis (magenta tongue), seborrheic dermatitis, and normochromic, normocytic anemia associated with pure red blood cell aplasia of the bone marrow. However, some of these symptoms, such as glossitis and dermatitis, when encountered in the field may have resulted from other complicating deficiencies.

Toxicity

Probably as a result of its limited solubility and limited gastric absorption, no adverse effects have been associated with ingestion of riboflavin appreciably above RDA levels. One study reported no short-term side effects in 49 patients treated with 400 mg/day of riboflavin with meals for at least 3 months.[500] Because of a lack of data for risk assessment, no tolerable upper intake level has been proposed for riboflavin.[170]

Laboratory Assessment of Status

Riboflavin status is assessed by (1) determination of urine riboflavin excretion, (2) a functional assay using the activation coefficient of stimulation of the enzyme glutathione reductase by FAD, or (3) direct measurement of riboflavin or its metabolites in plasma or erythrocytes. The advantages and disadvantages of functional or direct methods have been discussed in the section on thiamine.

Urinary riboflavin can be measured using fluorometric and microbiological procedures, but for specificity, HPLC combined with fluorometric detection is the method of choice.[104] Under conditions of adequate intake, the amount excreted per day is more than 120 μg or 80 μg/g creatinine. The rate of excretion expressed as μg/g creatinine is greater for children than for adults. Conditions causing negative nitrogen balance and the administration of antibiotics and certain psychotropic drugs (phenothiazine derivatives) increase urinary riboflavin as a consequence of tissue depletion and displacement. A load return test may augment the reliability, but is more cumbersome.

A commonly used method for assessing riboflavin status uses the determination of FAD-dependent glutathione reductase activity in freshly lysed erythrocytes.[495] This enzyme-based assay has been chosen for the majority of surveys of riboflavin status. Most methods measure the rate of change of absorbance at 340 nm caused by the oxidation of NADPH and have been automated to give rapid throughputs and CVs of less than 2% within run, though some have used fluorescence detection with increased sensitivity.[90] Potential problems are that in long-standing riboflavin deficiency the apoenzyme activity may be reduced, possibly leading to a misleading activation coefficient calculation, and that in patients with glucose-6-phosphate deficiency, a misleadingly low activation coefficient may be measured, possibly caused by enhanced binding of FAD to the apoenzyme.[450]

Direct measurement of riboflavin, FMN, and FAD in plasma or erythrocytes may be made by HPLC, usually with fluorescence detection after protein precipitation[90] or by capillary zone electrophoresis with laser-induced fluorescence detection (CZE-LIF).[438] In a study of riboflavin status and FMN and FAD concentrations in plasma and erythrocytes from elderly subjects at baseline and after low-dose riboflavin supplementation, using both activation coefficient measurements and CE-LIF, it was concluded that concentrations of all B_2 vitamers except plasma FAD are potential indicators of vitamin B_2 status, and that plasma riboflavin and erythrocyte FMN may be useful in the assessment of vitamin B_2 status in population studies.[262]

Reference Intervals

The reference interval for erythrocyte riboflavin using a fluorometric method[311] is 10 to 50 μg/dL (266 to 1330 nmol/L).[574] The reference interval for serum or plasma levels of riboflavin is 4 to 24 μg/dL (106 to 638 nmol/L).[186,574] Guidance reference intervals for the activation coefficient of erythrocyte glutathione reductase by FAD are 1.20 (adequacy), 1.21 to 1.40 (marginal deficiency), and 1.41 and above (deficiency).[32]

Vitamin B_6—Pyridoxine, Pyridoxamine, and Pyridoxal

Pyridoxine (pyridoxol), pyridoxamine, and *pyridoxal* are the three natural forms of vitamin B_6. They are converted to pyridoxal phosphate, which is required for the synthesis, catabolism, and interconversion of amino acids.

Chemistry

The vitamin B_6 group comprises three natural forms: *pyridoxine* (pyridoxol) *(PN), pyridoxamine (PM),* and *pyridoxal (PL),* which are 4-substituted 2-methyl-3-hydroxyl-5-hydroxymethyl pyridines (Figure 30-13). During metabolic conversions, each vitamer becomes phosphorylated at the 5-hydroxymethyl substituent. Although both pyridoxamine-5′-phosphate (PMP) and pyridoxal-5′-phosphate (PLP, P-5′-P) interconvert as coenzyme forms during aminotransferase (transaminase)-catalyzed reactions, PLP is the coenzyme form that participates in the large number of B_6-dependent enzyme reactions.

Dietary Sources

Vitamin B_6 is widely distributed in animal and plant tissues where the phosphorylated forms, and particularly PLP, predominate. Meats, poultry, and fish are good sources, as are yeast, certain seeds, bran, and bananas; somewhat more limited sources are milk, eggs, and green leafy vegetables.[295] In the United States and some other countries, fortified ready-to-eat cereals are the main dietary source of vitamin B_6. The common commercial form of the vitamin is pyridoxine hydrochloride, which is a water-soluble, white, crystalline solid. Solutions of the B_6 vitamers are decomposed by light, especially in the ultraviolet region at neutral to alkaline pH. The reactive aldehyde function of PLP leads to significant loss during thermal processing of foods.[210]

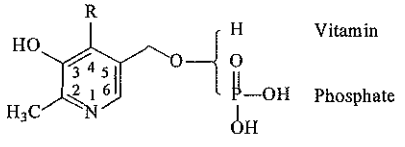

Figure 30-13 Free and phosphorylated forms of vitamin B_6. R = CH_2OH for pyridoxine, CH_2NH_2 for pyridoxamine, and CHO for pyridoxal.

Absorption, Transport, Metabolism, and Excretion

Food sources of animal origin contain mainly PLP with some PMP, whereas plant sources also contain pyridoxine-5′-glucoside, which is absorbed in a different manner. The phosphorylated sources are hydrolyzed by the intraluminal action of intestinal alkaline phosphatase, but pyridoxine-5′-glucoside is less effectively hydrolyzed by nonspecific glycosidase within cells, and some pyridoxine-5′-glucoside can be absorbed intact and hydrolyzed in various tissues.[251] The nonphosphorylated vitamers are readily absorbed by the mucosal cells by a process of passive diffusion, which does not appear to be limited by load.[227] Here, as in other cells requiring vitamin B_6, the unphosphorylated vitamers may be "metabolically trapped" as the phosphorylated forms by cytoplasmic pyridoxal kinase responsible for catalyzing the ATP-dependent phosphorylation of all three vitamin forms. Transport to the liver via the portal vein is by the unphosphorylated form.

Figure 30-14 shows the intracellular metabolism of vitamin B_6. Most cells contain a cytosolic FMN-dependent, pyridoxine (pyridoxamine)-5′-phosphate oxidase responsible for catalyzing the oxygen-dependent conversion of pyridoxine phosphate and pyridoxamine phosphate to PLP (and hydrogen peroxide).[578] PLP can enter directly into subcellular organelles, such as hepatocyte mitochondria,[351] and can bind for catalytic function with numerous specific apoenzymes throughout the cell. The erythrocyte, in addition, traps PLP as a conjugate Schiff base with hemoglobin.[375] Vitamin B_6 in muscle accounts for 80% of body stores, mostly as PLP bound to glycogen phosphorylase.[56] Total body stores of vitamin B_6 are thought to be about 1 mmole.

Release of free vitamin, mainly pyridoxal, occurs when physiological nonsaturating levels of vitamin are absorbed. Here the phosphates are hydrolyzed by nonspecific alkaline phosphatase located on the plasma membrane of cells. Some PLP is also released into the circulation by the liver.[578] Because the reactive aldehyde is capable of forming Schiff bases with amino groups, PLP in plasma is more tightly complexed to proteins—mostly albumin—than is pyridoxal, which forms an intramolecular hemiacetal between the 4-formyl and 5-hydroxymethyl functions. Although PLP is the principal tissue form of vitamin B_6 and pyridoxal constitutes much of the circulating vitamin, the main catabolite excreted in urine is 4-pyridoxic acid (4-PA), which is formed by the action of the FAD-dependent general liver aldehyde oxidase and especially by NAD-specific aldehyde dehydrogenase, which is found in most tissue.

Functions

As coenzyme PLP, vitamin B_6 functions in more than 100 reactions that embrace the metabolism of macronutrients, such as proteins, carbohydrates, and lipids.[326,369] Especially diverse are PLP-dependent enzymes that are involved in amino acid metabolism. By virtue of the ability of PLP to condense its 4-formyl substituent with the α-amino group of an amino acid to form an azomethine (Schiff base) linkage, a conjugated double-bond system, extending from the α-carbon of the amino acid to the pyridinium nitrogen in PLP, results in reduced electron density about the α-carbon. This configuration potentially weakens each of the bonds from the amino acid α-carbon to the adjoined hydrogen, carboxyl, and side-chain functions. A given apoenzyme then locks in a particular configuration of the coenzyme-substrate compound, such that maximal overlap of the bond to be broken will occur with the resonant, coplanar, electron-withdrawing system of the coenzyme complex. Aminotransferases affect rupture of the α-hydrogen bond with the ultimate formation of an α-keto acid and pyridoxamine-5′-phosphate; this reversible reaction provides an interface between amino acid metabolism and that of ketogenic and glucogenic reactions (see Chapter 21).

Other examples of PLP-requiring enzymes are the amino acid decarboxylases that lead to formation of amines, including several that are functional in nervous tissue (e.g., epinephrine, norepinephrine, serotonin, and γ-aminobutyrate); cysteine desulfhydrase and serine hydroxymethyltransferase, which use PLP to effect the loss or transfer of amino acid side chains; phosphorylase, which catalyzes phosphorolysis of the α-1,4-linkages of glycogen; and cystathione beta-synthase in the transsulfuration pathway of homocysteine. Additionally the biosynthesis of heme depends on the early

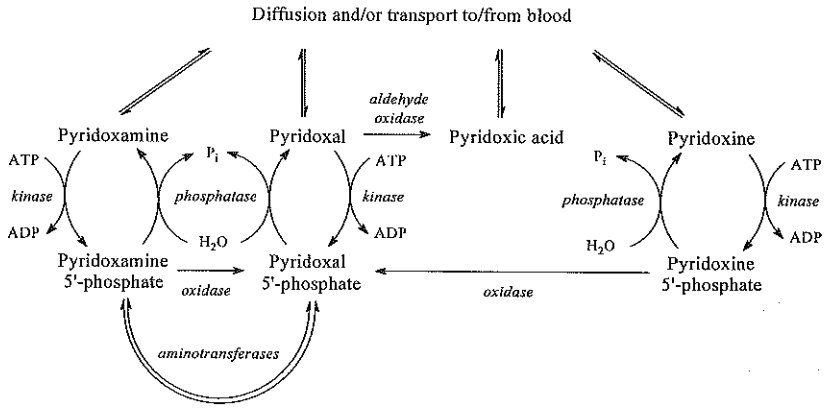

Figure 30-14 Metabolism of vitamin B_6.

formation of 5-aminolevulinate from PLP-dependent condensation of glycine and succinyl-CoA, followed by decarboxylation, and an important role in lipid metabolism is the PLP-dependent condensation of L-serine with palmitoyl-CoA to form 3-dehydrosphinganine, a precursor of sphingomyelins. Therapeutically, vitamin B_6 has been used in the treatment of some intractable seizures in neonates and infants,[204] in other vitamin B_6–responsive inborn errors of metabolism,[41] and in the carpal tunnel syndrome.[254]

Requirements and Reference Nutrient Intakes

Requirements for vitamin B_6 are complicated by (1) differences in protein intake, (2) the probable provision of a fraction of the necessary quantity through bacterial synthesis in the intestinal tract, (3) the use of alcohol and oral contraceptives, and (4) the infrequent cases in which extra requirements are apparent.[169,327] Estimates of requirements with some margin of safety have been based on the production and cure of clinical signs of deficiency but more often on biochemical parameters. The latter include the determination of the urinary excretion of vitamin B_6 and 4-PA or xanthurenic acid after a tryptophan load test, the plasma levels of PLP, and red blood cell transaminase activity.[170] A ratio of 0.016 mg of vitamin B_6/g of protein intake has been suggested for normal adults and may be extrapolated to children and adolescents. Recommendations (1998) have proposed RDAs of 0.5 mg/day for children 1 to 3 years, 0.6 mg/day for children 4 to 8 years, 1.0 mg/day for children 9 to 13 years, 1.3 mg/day for boys 14 to 18 years, 1.3 mg/day for men to age 50 years, and 1.7 mg/day for men over 50 years. Girls 14 to 18 years have an RDA of 1.2 mg/day; women 19 to 50 years, 1.3 mg/day; and women over 50 years, 1.5 mg/day.[170] An addition of 0.6 mg B_6 per day is suggested for pregnant women to match the increased protein allowance during gestation. During lactation, an additional 0.5 mg/day is recommended to accommodate for extra protein intake and provide a level of 0.10 to 0.25 mg/L of the vitamin in milk, which is adequate for the breast-fed infant.

Intravenous Supply

The recommended intravenous supply of vitamin B_6 has been increased from 4 mg/day to 6 mg/day for adults to ensure adequate amounts in patients who are sometimes receiving quite large amino acid intakes.[243] This is usually provided as pyridoxine hydrochloride.

Deficiency

A deficiency of vitamin B_6 alone is uncommon, and it is more usual to expect the problem to occur in association with deficits in other vitamins of the B-complex. As with other water-soluble vitamins that function as coenzymes, the relative affinity of the coenzyme for a given apoenzyme and the extent to which a particular holoenzyme-catalyzed reaction is essential are reflected in the progressive symptomatology of deficiency of the vitamin. Investigations of the consequences of vitamin B_6 deficiency in the human use diets deficient in the vitamin and/or diets containing an antagonist, usually 4′-deoxypyridoxine.[112] There are, however, instances in which drug interactions have led to hypovitaminosis of B_6.[371] The antituberculosis drug isoniazid (isonicotinic acid hydrazide) forms hydrazones with pyridoxal and PLP. As with other "carbonyl reagents," such compounds not only cause loss by displacement and urinary excretion, but the Schiff bases formed with pyridoxal inhibit pyridoxal kinase,[372] and the PLP Schiff bases may additionally inhibit some PLP-dependent enzymes.[578] Penicillamine (β-dimethyl cysteine), used in treatment of patients with Wilson's disease in an attempt to decrease the damaging levels of copper found in liver, inactivates PLP by forming a thiazolidine derivative.[280] Other drugs that can cause vitamin B_6 deficiency include the antiparkinsonian drugs benserazide and carbidopa, which react by forming hydrazones,[40] and theophylline.[200]

There are several vitamin B_6–responsive inborn errors of metabolism[41] that include (1) cases of infantile convulsions in which the apoenzyme for glutamate decarboxylase has a poor affinity for the coenzyme; (2) a type of chronic anemia in which the number but not morphological abnormality of erythrocytes is improved by pyridoxine supplementation; (3) xanthurenic aciduria in which affinity of the mutant kynureninase for PLP is decreased; (4) primary cystathioninuria caused by similarly defective cystathionase; and (5) homocystinuria in which there is less of the normal cystathionine synthetase.[403] In these cases increased levels (200 to 1000 mg/day) of administered vitamin B_6 are required for life.[477] Low vitamin B_6 status (together with low vitamin B_{12} and folate status) in humans has been linked to hyperhomocysteinemia and as an independent risk factor for cardiovascular disease.[121,316]

Biochemical markers of vitamin B_6 deficiency occur early and become more marked as the deficiency progresses.[327,495,578] Plasma levels of PLP and urinary output of B_6 and 4-PA decrease within 1 week of removal of vitamin from the diet. Because liver kynureninase activity is decreased, there is increased xanthurenic acid in urine. Aminotransferase activity in serum and red blood cells also decreases. Clinically, electroencephalographic abnormalities appear within 3 weeks and epileptiform convulsions are a common finding in young vitamin B_6–deficient subjects. In addition, skin changes occur, including dermatitis with cheilosis and glossitis. Hematological manifestations may include a decrease in the number of circulating lymphocytes and possibly a normocytic, microcytic, or sideroblastic anemia.

Toxicity

Although no adverse effects have been observed with high intakes of vitamin B_6 from food sources, high oral supplemental doses can have neurotoxic and photosensitive effects. The first reported cases in humans were a series of 7 patients who had taken between 2 and 6 g of pyridoxine per day for up to 40 months. Four of these patients were unable to walk

and all showed severe sensory neuropathy of the extremities, though the majority of the symptoms were reversed on stopping the pyridoxine.[497] None of the subsequent studies showed any evidence of sensory nerve damage at intakes below 200 mg/day. Based on the end point of development of sensory neuropathy, 1998 recommendations have set a tolerable upper intake level of 100 mg/day for adults.[170]

Laboratory Assessment of Status

As with the other B vitamins that act as coenzymes, biochemical assessment of vitamin B_6 can be made by direct chemical analysis of the vitamer or its metabolites, or by functional means. Measurements that have been used are PLP in plasma or red cells, its metabolite 4-PA in urine or plasma, the activity and activation coefficient of the red cell aminotransferases (aspartate and alanine), and the tryptophan load metabolite excretion test.[32] As no single marker adequately reflects status, a combination of these markers offers the best approach.

Direct assessment was originally made by microbiological techniques using specific strains of *Saccharomyces carlsbergensis* for all 3 natural vitamers, *Enterococcus faucium* for pyridoxal and pyridoxamine, and *Lactobacillus casei* for pyridoxal. Levels of 20 μg of vitamin B_6 per gram creatinine in urine are considered indicative of marginal or inadequate dietary intake of the vitamin. Plasma PLP and plasma or urine 4-PA are most commonly measured by HPLC, PLP with fluorescence detection following precolumn fluorophore formation either as a semicarbazone,[582] or a pyridoxic acid phosphate,[387] and 4-PA with its natural fluorescence. During deficiency, the level of 4-PA will drop well below the normal level of at least 0.8 mg/day in urine. Using ion-pair reversed-phase chromatography,[63] plasma vitamin B_6 vitamers (PLP, PL, PN, PMP, PM, and 4-PA) were measured in 90 patients undergoing coronary angiography before and after treatment with pyridoxine, 40 mg daily for up to 84 days. PLP, 4-PA, and to a lesser degree PL were found to be the predominant B_6 metabolites in pretreatment plasma. After treatment, PN was also detectable, and PN and PL showed the largest increases in concentration. Increases in plasma concentrations of PLP, PL, and 4-PA occurred within 3 days of supplementation and were steady for the remainder of the study period. Other direct measurements have used recombinant enzyme technology. A homogenous, nonradioactive recombinant enzymatic method for PLP has been described that uses 5 μL of plasma, has a detection limit of 5 nmol/L, and may be applicable to adaptation to an automated analyzer.[228]

Functional assessment of vitamin B_6 status may be made by measuring the activity of red cell aspartate (or alanine) aminotransferase, and its activation coefficient on incubation with PLP, though as the apoenzyme is highly unsaturated with PLP, the results obtained have more variability than corresponding methods for vitamins B_1 and B_2 and are thus considered less useful. Activation coefficients of less than about 1.5 for aspartate aminotransferase and 1.2 for alanine aminotransferase are considered normal but may depend somewhat on the assay method used. Measurement of urinary tryptophan metabolites, particularly xanthurenic acid, following an oral load (2 to 5 g) of L-tryptophan, is one of the most common indices used in studies of vitamin B_6 nutriture, because changes can be recognized early and measurements are relatively easy. Amounts of xanthurenate well above the normal (about 25 mg/day) are seen in vitamin B_6 deficiency. Levels of other metabolites, such as kynurenic acid and 3-hydroxykynurenine, are also increased.

Reference Intervals

A guidance reference interval for plasma PLP is 5 to 30 ng/mL (20 to 121 nmol/L).[464] Plasma levels less than 5 ng/mL (20 nmol/L) are judged deficient. Guidance values for other vitamin B_6 metabolites have been published elsewhere.[495]

Vitamin B_{12}—Cyanocobalamin

Vitamin B_{12}, also known as cyanocobalamin, is a water-soluble hematopoietic vitamin that is required for the maturation of erythrocytes.

Chemistry

Vitamin B_{12} is one of the most structurally complex small molecules produced by nature, whose biosynthetic pathway has been extensively studied and elucidated.[613] The generic term vitamin B_{12} refers to a group of physiologically active substances chemically classified as cobalamins or corrinoids. They are composed of tetrapyrrole rings surrounding central cobalt atoms and nucleotide side chains attached to the cobalt. The cobalamin tetrapyrrole ring, exclusive of cobalt and other side chains, is called a corrin. All compounds containing this corrin nucleus are corrinoids. The cobalt-corrin complex is termed cobamide. In cobalamins, 5,6-dimethylbenzimidazole riboside is bound to the cobalt atom by one of its imidazole nitrogens and its 2′-ribose carbon is linked with an ester of aminoisopropanol and propionic acid to the corrin ring (Figure 30-15).

Cobalamins differ in the nature of additional side groups bound to cobalt. Examples are methyl (methylcobalamin), 5′-deoxyadenosine (deoxyadenosyl [short form, adenosyl] cobalamin, or coenzyme B_{12}), hydroxyl (hydroxocobalamin), H_2O (aquocobalamin, or vitamin B_{12b}), and cyanide (cyanocobalamin). Cyanocobalamin is a stable compound that forms dark red, needlelike crystals; it is the reference compound for measuring serum cobalamin concentration. Less stable serum cobalamins may be converted to this compound for quantitation. The predominant physiological form of cobalamin in serum is methylcobalamin, whereas that in cytosols is adenosylcobalamin. It is recommended that the term vitamin B_{12} be used as the generic descriptor for all corrinoids exhibiting qualitatively the biological activity of cyanocobalamin.[126] Cyanocobalamin has a molecular weight of 1355 Da and a solubility of 12 g/L in water at 20 °C. It is also soluble in lower alcohols and aliphatic acids, but is insoluble in acetone, ether, and chloroform. It is grad-

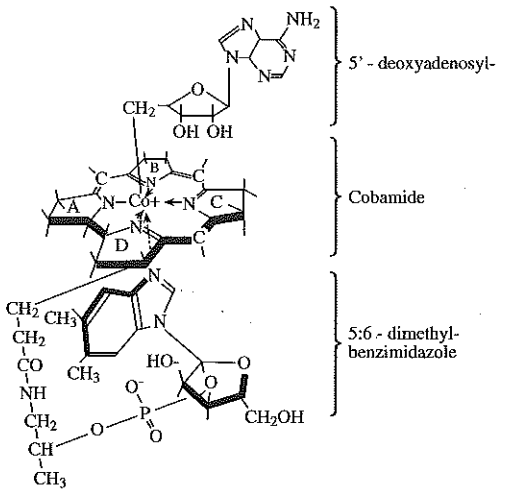

Figure 30-15 The structure of 5'-deoxyadenosyl cobalamin. *(Modified from Chanarin I: The megaloblastic anemias, 2nd edition, Oxford: Blackwell Scientific, 1979.)*

ually destroyed on exposure to light.[126] Aqueous solutions of cyanocobalamin exhibit a distinctive absorption spectrum with maxima at 278, 361, and 550 nm, with absorptivity coefficients of 115, 207, and 63 at these maxima, respectively. The spectrum is independent of pH but changes when cyanocobalamin binds to intrinsic factor (IF). Because of its stability in aqueous solutions and its distinct absorption spectrum, accurate concentrations of cyanocobalamin can be prepared and used as calibrators for the measurement of serum cobalamin levels.

Dietary Sources

All vitamin B_{12} is ultimately the product of microbial synthesis, and because plants do not use the vitamin, the main dietary sources are meat and meat products, dairy products, fish and shellfish, and fortified ready-to-eat cereals.[170]

Absorption, Transport, Metabolism, and Excretion

The uptake of vitamin B_{12} from the intestine into the circulation is a complex mechanism, involving five separate vitamin B_{12}–binding molecules, receptors, and transporters.[484] The vitamin B_{12} released from food in the stomach is bound to haptocorrin (R protein, a salivary protein), and travels with it into the intestine where the haptocorrin is digested by pancreatic enzymes. The liberated vitamin B_{12} then binds to IF, a glycoprotein with a molecular weight of approximately 50 kDa, which is produced by the gastric mucosa. When the vitamin B_{12}–IF complex reaches the distal ileum, it is bound by receptors on the surface of mucosal epithelial cells and then enters the cells. Within the mucosal epithelial cells, the vitamin B_{12}–IF complex is dissociated with the vitamin B_{12}, then binding with transcobalamin II (TcII). The B_{12}-TcII complex is then transported across the cell membrane bound to a TcII-receptor and then released into the plasma of the mucosal capillaries and subsequently to the blood in the portal vein.[222] Almost all of the vitamin B_{12} is taken up by hepatocytes as the blood in the portal vein passes through the liver. It is stored in the liver and released to plasma to meet physiological demands. If the quantity of vitamin B_{12} exceeds the capacity of hepatocyte receptors, most of the excess is excreted by the kidneys. Normally, approximately 1 mg of vitamin B_{12} is stored in the liver, a quantity equivalent to the daily metabolic requirement for 2000 days. Thus when the dietary supply of vitamin B_{12} is interrupted or mechanisms of absorption are impaired, vitamin B_{12} deficiency does not become evident for 5 years or more.

IF is a glycoprotein with a molecular weight of approximately 50 kDa, secreted by the parietal cells of the stomach. Many other substances can bind vitamin B_{12}, but no other known substance has the property of transporting it across the intestinal wall. One molecule of IF binds one molecule of vitamin B_{12}. The gastric secretion of IF is stimulated by food, histamine, and gastrin; it is inhibited by vagal blockade. The ileal receptor for the IF–vitamin B_{12} complex has an association constant of approximately 5×10^9 mol/L between pH 6.4 and 8.4. The binding does not appear to be specific for the configuration of the vitamin B_{12} molecule, because complexes of IF with various analogues of vitamin B_{12} bind equally well to the ileal receptors.

The most important vitamin B_{12} transport protein in plasma is TcII, a β-globulin. It is synthesized mainly in the liver but also in other tissue. TcII is a polypeptide with a molecular weight of approximately 43 kDa; it has a single vitamin B_{12} binding site per molecule.[511] TcII is less specific for vitamin B_{12} than is IF; it also binds cobalamins that are physiologically inactive. TcII transports vitamin B_{12} to receptors on cell membranes throughout the body. Binding is very rapid: if TcII–vitamin B_{12} is injected intravenously, it is almost completely cleared in one passage through tissue, mostly by the liver.[222] The TcII–vitamin B_{12} complex enters the cell by pinocytosis. Lysosomal proteolysis degrades TcII and releases the vitamin B_{12}. Unbound vitamin B_{12} can also enter the tissue cells, but the process is much less efficient.[222]

Two types of vitamin B_{12} binders are found in human gastric juice, one with slow (S) and one with rapid (R) mobility in zone electrophoresis. The slow component is IF, and the rapid component is R protein. Immunologically identical R proteins are found in plasma, amniotic fluid, milk, saliva, ascitic fluid, and granulocytes. However, this granulocyte-derived protein can be differentiated from the other R proteins electrophoretically. It is called *transcobalamin III*, whereas the R protein from other sources is designated *transcobalamin I*. Collectively, these two binders are called *cobalophilins*. They are glycoproteins with molecular weights between 60 and 150 kDa. Heterogeneity of R proteins may be due to variations in the carbohydrate moieties (sialic acid residues) rather than in the apoproteins. They have one binding site per molecule and bind vitamin B_{12} analogues to some extent. In gastric juice at pH 2, the cobalophilins have much greater affinity than IF and bind

almost all vitamin B_{12}. It has been postulated that cobalophilins aid in host defense against bacteria by depriving them of access to vitamin B_{12}. However, the physiological function of these proteins is unknown.

Vitamin B_{12} is continually secreted in the bile, but most of this is reabsorbed and available for metabolic functions. If circulating vitamin B_{12} concentrations exceed the binding capacity of the blood, the excess will be excreted in the urine, but in most circumstances the highest losses of vitamin B_{12} occur through the feces.

Functions

Vitamin B_{12} is required in coenzyme form for more than 12 different enzyme systems.[36] In humans it is required in (1) adenosylcobalamin, coenzyme to L-methylmalonyl-CoA mutase in the conversion of L-methylmalonyl CoA to succinyl-CoA; and (2) methylcobalamin, coenzyme to methionine synthase in the conversion of homocysteine to methionine. In the former reaction (Figure 30-16), the mutase is a mitochondrial matrix enzyme that binds 2 mol of adenosyl-cobalamin (Cbl) per dimer[350] and participates in a complex reaction using radical chemistry.[27] The conversion of L-methylmalonyl-CoA to succinyl-CoA links propionyl-CoA, which is formed from amino acids, such as valine, isoleucine, and methionine, and odd-chain fatty acids with the tricarboxylic acid (TCA) cycle. Congenital defects of the mutase synthesis or inability to synthesize adenosyl-Cbl result in life-threatening methylmalonic aciduria and metabolic ketoacidosis. In the latter reaction (Figure 30-16), methylcobalamin serves as an intermediate in the transfer of a methyl group from 5-methyltetrahydrofolate to homocysteine for the formation of methionine. Methionine is required for the protein synthesis and as the methyl donor, *S*-adenosylmethionine. Congenital defects in methionine synthase or the synthesis of methyl-Cbl result in severe hyperhomocysteinemia.[158]

Requirements and Reference Nutrient Intakes

The total body stores of vitamin B_{12} are estimated to be between 2 and 5 mg in the adult man,[4] of which about 1 mg is in the liver and a smaller amount in the kidney. There is thought to be a daily obligatory loss of vitamin B_{12} of about 0.1% of body pool, irrespective of size,[246] suggesting that a daily requirement to maintain stores would be 2 to 5 μg. The daily diet of Western countries contains between 5 and 30 μg of vitamin B_{12}, with average ingestion being 7 to 8 μg/day by adult men and 4 to 5 μg/day by adult women. Additional small amounts may be available from vitamin B_{12} synthesis by intestinal microorganisms. Of the amount ingested, between 1 and 5 μg is absorbed.

The RDA for vitamin B_{12} is based on the amount necessary for the maintenance of hematological status and normal serum vitamin B_{12} concentrations, and assumes 50% absorbance of ingested vitamin B_{12}. The RDA for adults (19 to 50 years) has been set at 2.4 μg/day, with an increase to 2.6 μg/day in pregnancy and to 2.8 μg/day in lactation. RDAs for children are 0.9 μg/day at 1 to 3 years, 1.2 μg/day at 4 to 8 years, 1.8 μg/day at 9 to 13 years, and 2.4 μg/day at 14 to 18 years. Because 10% to 30% of older persons may be unable to absorb naturally occurring vitamin B_{12}, it is recommended that those older than 50 years meet their RDA mainly by consuming foods fortified with vitamin B_{12} or with a vitamin B_{12}–containing supplement.[170]

Intravenous Supply

The recommended intravenous intake for adults is 5 μg/day as cyanocobalamin, an amount in excess of the oral recommendation that will more than meet requirements.[9]

Deficiency

Deficiency of vitamin B_{12} in humans is associated with megaloblastic anemia and neuropathy. The most common cause of vitamin B_{12} deficiency is *pernicious anemia*, an autoimmune disease in which chronic atrophic gastritis results from antibodies to gastric parietal cells and IF, directed against gastric parietal cell H^+/K^+-ATPase.[575] A 1996 population study showed that 1.9% of persons over 60 years old have undiagnosed pernicious anemia, though the diagnosis is made most commonly in young to middle-aged black women (mean age 53 years) and in middle-aged to elderly whites.[94] Pernicious anemia may also occur in children because of either failure of IF secretion or secretion of biologically inactive IF. Other groups at risk of vitamin B_{12} deficiency include those (1) older than 65 years of age; (2) with malabsorption; (3) who are vegetarians; (4) with autoimmune disorders; (5) taking prescribed medication known to interfere with vitamin absorption or metabolism, including nitrous oxide, phenytoin, dihydrofolate reductase inhibitors, metformin, and proton pump inhibitors; and (6) infants with suspected metabolic disorders.

Figure 30-16 Participation of cobalamin coenzymes in human metabolism.

Intestinal malabsorption of vitamin B_{12} may be caused by gastrectomy or ileal resection, with an inverse relationship between the length of ileum resected and the absorption of vitamin B_{12}. Other causes of malabsorption are tropical sprue, inflammatory disease of the small intestine, intestinal stasis with overgrowth of colonic bacteria, which consume the vitamin B_{12} ingested by the host, and HIV infection. Another cause of vitamin B_{12} malabsorption is failure to extract cobalamin from food. Some patients fail to absorb cobalamin bound to food, whereas absorption of nonfood-bound cobalamin in the Schilling test is unimpaired. This is particularly a problem in patients with compromised gastric status[92] or early in the course of development of pernicious anemia.

Vegetarians have a lower intake of vitamin B_{12} than omnivores, and though clinical signs of deficiency are uncommon, biochemical markers of status indicate functional vitamin B_{12} deficiency. In a study of 66 lactovegetarians or lacto-ovo vegetarians, 29 vegans, and 79 omnivores, the incidence of low holotranscobalamin II was 77%, 92%, and 11%, respectively, in the 3 groups; of elevated methylmalonic acid, 68%, 83%, and 5%; and of elevated total homocysteine, 38%, 67%, and 16%. Consequently, these results indicate that the health aspects of prolonged hyperhomocysteinemia may have to be addressed.[245]

A large number of disorders are associated with cobalamin deficiency in infancy or childhood. Of these, the most commonly encountered is the Imerslund-Graesbeck syndrome, a condition that is characterized by inability to absorb vitamin B_{12}, with or without IF, and proteinuria. It appears to be due to an inability of intestinal mucosa to absorb the vitamin B_{12}–IF complex. The second most common of these is congenital deficiency of gastric secretion of IF. Very rarely, congenital deficiency of vitamin B_{12} in a breast-fed infant is due to deficiency of vitamin B_{12} in maternal breast milk as a result of unrecognized pernicious anemia in the mother. This is rare because most women with undiagnosed and untreated pernicious anemia are infertile. Additionally, there are some rare methylmalonic acidemias (acidurias) caused by inborn errors in homocysteine and methionine metabolism that are responsible for disorders in vitamin B_{12} status.[157]

The hematological effects of vitamin B_{12} deficiency are indistinguishable from those of folate deficiency. The classical morphological changes in the blood, in approximate order of appearance are: hypersegmentation of neutrophils, macrocytosis, anemia, leukopenia, and thrombocytopenia, with megaloblastic changes in bone marrow accompanying the peripheral blood changes. The cause of the hematological abnormalities is thought to be the imbalance of decreased deoxyribonucleic acid (DNA) synthesis and adequate ribonucleic acid (RNA) synthesis caused by the secondary block in folate metabolism caused by the vitamin B_{12} deficiency.[7] Many immature cells die in the bone marrow, possibly by apoptosis, leading to a release of bilirubin and lactate dehydrogenase (LD) into the blood. This is termed ineffective erythropoiesis. All of the bone marrow lesions can be reversed by vitamin B_{12} treatment.

In addition to hematological changes, vitamin B_{12} deficiency can lead to a demyelinating disorder of the central nervous system in man. Serious and often irreversible neurological disorders can occur, such as burning pain or loss of sensation in the extremities, weakness, spasticity and paralysis, confusion, disorientation, and dementia. This condition has been given the name *subacute combined degeneration of the spinal cord*. Neurological symptoms may occur without any discernible hematological changes in the blood, and indeed an intriguing inverse relationship between the hematological and the neurological has been observed.[239] The incidence of neurological complications is between 75% and 90% of all individuals with clinically observable vitamin B_{12} deficiency, and may in about 25% of cases be the only clinical manifestation of deficiency. The mechanism of the disorder is uncertain though there is some indirect evidence that suggests that disorders of both enzyme systems requiring vitamin B_{12} coenzymes are necessary before neurological symptoms occur.[158] The response of neurological symptoms to vitamin B_{12} replacement is often dependent upon the duration of the symptoms. Vitamin B_{12} deficiency may also be associated with other mainly gastrointestinal complications, such as glossitis of the tongue, appetite and weight loss, flatulence and constipation, mental changes, and infertility.[7]

Toxicity

No adverse effects have been associated with excess vitamin B_{12} intake from food or supplements in healthy people. Daily oral doses of up to 2 mg of cyanocobalamin can be used for treatment of deficiency in those who can tolerate oral supplementation.[320] There are insufficient data in the literature to propose a tolerable upper intake level for vitamin B_{12}.[170]

Laboratory Assessment of Status

Both direct and indirect (functional) methods are available for assessing vitamin B_{12} status. The indirect tests include assays for urinary and serum concentrations of methylmalonic acid, plasma homocysteine, the deoxyuridine suppression test, and the vitamin B_{12} absorption test. Cytochemical staining of red blood cell (RBC) precursors and the test for IF blocking antibodies are also ancillary methods for assessing vitamin B_{12} status.

Microbiological, competitive protein binding (CPB), and immunometric assays have been used for the quantitation of serum vitamin B_{12}. The microbiological assays have largely been replaced by the other, more convenient and precise methods though they remain reference methods for the determination of biologically active vitamin B_{12}. The most widely used procedures use either *Euglena gracilis, Lactobacillus leishmannii,* or a mutant of *Escherichia coli,* though each of these organisms is susceptible to growth inhibition by antibiotics or other drugs, such as methotrexate, that may

be in a patient's serum. Furthermore, these assays require at least 24 hours to establish adequate growth of the microorganism. However, the use of microtiter enzyme-linked immunosorbent assay (ELISA) plate technology has increased the utility of some microbiological assays.[301]

Commercial kits are available for the CPB assays of vitamin B_{12}. The vitamin B_{12} binder used is often nonhuman IF, usually obtained from hog stomach. If the IF is not highly purified, it may contain R proteins, which bind not only vitamin B_{12} but also related metabolically inactive compounds, giving higher values. IF must therefore be either highly purified or have cobinamide (a vitamin B_{12} analogue) added to the IF to saturate all binding sites on the R proteins. Cobinamide is not bound by IF.

In a widely used CPB assay, vitamin B_{12} (cobalamin) competes with ^{57}Co-labeled cobalamin for a limited number of binding sites on IF. Some assays require a preliminary step in which the specimen is boiled in a buffered solution containing dithiothreitol, KCN, and ^{57}Co-labeled tracers to release vitamin B_{12} from endogenous binding proteins. Alternatively, other procedures irreversibly denature endogenous binding proteins by increasing the pH from 12 to 13 and then readjusting the pH to 9.3 before the binding reagent is added. Subsequent separation of bound and free folate and vitamin B_{12} is achieved by contact with dextran-coated charcoal, which absorbs the free (unbound) molecules, leaving protein-bound vitamin B_{12} in the solution.

Most immunometric methods use solid phase separation by immobilizing the IF binder on beads or magnetic particles. The free vitamin B_{12} then remains in the supernatant, and the bound analytes become part of the solid phase suspension. For simultaneous folate/vitamin B_{12} measurement, a gamma-scintillation counter that discriminates between the energy levels of ^{57}Co (for vitamin B_{12}) and ^{125}I (for folate) must be used.

Multiple automated and semiautomated systems are available for measuring vitamin B_{12} and folate, using, for example, chemiluminescence as a signal. The assays are standardized with a 7.5-minute incubation, magnetic particle separation, and acridium ester signal. The precision of automated systems allows specimens to be analyzed in singlet while maintaining CVs less than those found for the mean of duplicates of radioimmunoassays.

Indirect tests assess the functional adequacy of vitamin B_{12}. Serum methylmalonic acid concentration is increased when a lack of adenyl-Cbl causes a block in the conversion of methylmalonyl-CoA to succinyl-CoA. It is a sensitive test of status, being often the first analyte to be raised in subclinical vitamin B_{12} deficiency.[496] It has a further advantage in that it is unaffected by folate deficiency. Early methods for methylmalonic acid lacked sensitivity and specificity, a situation that has been resolved by the adoption of gas chromatographic–mass spectrometric methods,[542] though these require specialized handling. Plasma total homocysteine concentration is a sensitive indicator of vitamin B_{12} status, because methyl-Cbl is required for the remethylation of homocysteine to methionine, but is not specific, being elevated in deficiency of folate and vitamin B_6 and vitamin B_{12}. Plasma concentrations of total homocysteine can be reliably measured by HPLC with fluorescent or electrochemical detection, and enzymatic and capillary gas chromatography–mass spectroscopy methods.[495] Plasma samples for homocysteine analysis must be obtained soon after venipuncture to reduce preanalytical increases that occur on standing, though these can be minimized by the use of a fluoride–ethylenediaminetetraacetic acid (EDTA) tube. The increased screening of plasma total homocysteine concentrations as an independent risk factor for cardiovascular disease (see Chapter 26) may lead to the recognition of further cases of subclinical vitamin B_{12} deficiency.

The measurement of holotranscobalamin II is potentially useful as a specific marker of biologically available vitamin B_{12}, because only cobalamin bound to TcII is specifically available for uptake by all cells. Other methods have been described for the measurement of holotranscobalamin in serum, one using an immobilized monoclonal antibody to human transcobalamin, followed by measurement of released cobalamin by CPB.[584] This method is currently available as a commercial kit. The other method uses magnetic beads coated with cobalamin to precipitate apotranscobalamin followed by measurement of the holotranscobalamin in the supernatant by ELISA.[417] Though these methods are claimed to be precise and simple to perform, there remains doubt over the interpretation of the measured concentrations,[93] and over their sensitivity and specificity in the diagnosis of vitamin B_{12} deficiency.[342]

The deoxyuridine suppression test measures the effect of prior addition of deoxyuridine on the uptake of radiolabeled thymidine into the DNA of cultured bone marrow cells, peripheral blood lymphocytes, or whole blood. Normal samples that contain vitamin B_{12} can convert deoxyuridine to thymidine and therefore do not take up as much thymidine. Samples from patients who are deficient in vitamin B_{12} show less suppression than in normal patients. Because it is relatively time consuming, the deoxyuridine suppression test is not widely available for use as a diagnostic test.[556]

The Schilling test is primarily a test of vitamin B_{12} absorption and not of status, but it permits differentiation of causes of vitamin B_{12} deficiency (pernicious anemia or intestinal malabsorption). The proportion absorbed from orally administered ^{57}Co- or ^{58}Co-labeled vitamin B_{12} is measured by determining the radioactivity in feces, urine, or serum or by externally scanning the liver. The usual procedure is to measure radioactivity in a 24-hour urine sample, which is collected after oral administration of 0.5 μg of radioactive Co-labeled vitamin B_{12} after an overnight fast. In normal individuals, 8% or more of the dose administered is excreted in the urine, whereas in people with pernicious anemia, less than 7% (often 0% to 3%) is excreted. A confirmatory test for lack of IF requires ingestion of vitamin B_{12} and IF.[74]

Reference Intervals

Depending on the laboratory and the procedure used, reference intervals can vary widely. The WHO, in their report in 1968, defined a serum vitamin B_{12} concentration of less than 150 ng/L (110 pmol/L) as deficient, and one of 201 ng/L (147 pmol/L) or higher[619] as acceptable. A dietary and nutritional survey of British adults in 1990 published a reference interval of 206 to 678 ng/L (151 to 497 pmol/L).[209] The changes in serum vitamin B_{12} concentration as a function of age in healthy adults have been the subject of contradictory reports. Data from a study population in the United States (Framingham Study) showed an increased prevalence (40.5% of 222 subjects) of low serum vitamin B_{12} concentration (<258 pmol/L) in elderly subjects than in a control group of younger subjects (17.9% incidence).[335] Vitamin B_{12} concentrations within the reference interval may not necessarily reflect adequate vitamin B_{12} status, because serum concentrations may be maintained at the expense of tissue stores. Conversely, low serum vitamin B_{12} concentrations may not be indicative of vitamin B_{12} deficiency. Most of the vitamin B_{12} in serum is bound to TcI, which is released by granulocytes and has no functional role in transport of vitamin B_{12} to cells. Low serum vitamin B_{12} concentration may be due to a reduction in TcI as a consequence of low total granulocyte mass. This has been observed in benign neutropenia, multiple myeloma, and leukemic reticuloendotheliosis and may be expected in other conditions in which the bone marrow is hypoplastic, aplastic, or replaced by malignant cells.

Serum methylmalonic acid concentrations below 376 nmol/L have been considered acceptable in an elderly U.S. population,[335] as have concentrations below 320 nmol/L in a group of older Dutch subjects.[589]

Vitamin C—Ascorbic Acid

Vitamin C (L-ascorbic acid) serves as a reducing agent in several important hydroxylation reactions in the body.

Chemistry

As shown in Figure 30-17, the term vitamin C refers to all molecules that exhibit antiscorbutic properties in humans and includes both ascorbic acid and its oxidized form, dehydroascorbic acid (DHA). The vitamin C redox system comprises these molecules and the free radical intermediate, monodehydroascorbic acid,[288] the product of one-electron oxidation of ascorbic acid. L-ascorbic acid is the enol form of 2-oxo-L-gulofuranolactone, the enolic hydroxyl on ring carbon 3 having a pK_a of 4.2 and conferring its acidic nature. The vitamin is a white, crystalline solid that is readily soluble in water. Acidic solutions (below pH 3) show absorption maximum at 245 nm, whereas solutions of the ionized material (above pH 5) have an absorption peak at 265 nm. Ascorbic acid is a relatively strong reductant with an E_0' (pH 7) of +0.58 volt. The dehydro form is more labile than the reduced form to hydrolytic ring opening to yield 2,3-diketo-L-gulonic acid, which is not antiscorbutic.

L-Ascorbic acid Dehydroascorbic acid

Figure 30-17 L-ascorbic and dehydroascorbic acids. *(Modified from Row PB: Inherited disorders of folate metabolism. In Stanbury JB, Wyngaarden DS (eds): The metabolic bases of inherited disease, 5th edition, New York: McGraw-Hill, 1983.)*

Dietary Sources

Plants and most animals possess the ability to synthesize the vitamin from D-glucose via the lactones of D-glucuronic and L-gulonic acids; however, some mammals, including the human, lack L-gulonolactone oxidase, the enzyme that catalyzes the formation of 2-keto-L-gulonolactone, which spontaneously tautomerizes to L-ascorbic acid. Excellent sources of the vitamin are citrus fruits, berries, melons, tomatoes, green peppers, broccoli, brussels sprouts, and leafy green vegetables.[548] Losses during processing, especially with heat and aerobic conditions, can be considerable.

Absorption, Transport, Metabolism, and Excretion

Gastrointestinal absorption of ascorbic acid occurs by a combination of sodium-dependent active transport at low concentrations and by simple diffusion at high concentrations.[482] Between 70% and 90% of a usual dietary intake of ascorbic acid (up to 180 mg/day) is absorbed, falling to 50% or less at loads greater than 1 g/day.[292] The absorbed ascorbic acid moves rapidly from the intestinal cell into blood by a process of facilitated diffusion.[358] Ascorbate uptake by cells is mediated by specific transporters, ascorbate by the sodium-dependent transporters SVCT 1 and SVCT 2 and DHA via the facilitated-diffusion glucose transporters GLUT 1, 3, and 4.[332] Vitamin C is found in most tissues, but glandular tissues, such as the pituitary, adrenal cortex, corpus luteum, and thymus, have the highest amounts and the retina has 20 to 30 times the plasma concentration. DHA, once transported intracellularly, is reduced to ascorbate, and in plasma vitamin C exists predominantly as the ascorbate ion. Many cells, particularly the hepatic cells, neutrophils, mononuclear phagocytes, osteoblasts, and erythrocytes, are capable of DHA uptake and recycling to ascorbate, which maintains a human body pool of up to 2 g.[292] The biological half-life of vitamin C in an individual ranges from 8 to 40 days, with an average of about 16 days. Vitamin C is conserved during periods of low intake, absorption becoming maximum with minimum urinary excretion. Excretion of unchanged ascorbate occurs increasingly with increased dosage, with almost all of an injected dose more than 500 mg being excreted over 24 hours.[331] DHA that is not recycled may be irreversibly delactonized to 2,3-diketogulonic acid

and further degraded to oxalic acid for urine excretion. Other catabolic products of 2,3-diketogulonic acid are L-lyxonic acid, L-xylose, and L-threonic acid.

Functions

Ascorbic acid acts as a cofactor for a number of mixed function oxidases in processes in which it promotes enzyme activity by maintaining metal ions in their reduced form (particularly iron and copper). Its most clearly established and critical functional role is as a cofactor for protocollagen hydroxylase, the enzyme responsible for hydroxylation of prolyl and lysyl residues within nascent peptides in connective tissue proteins.[288] Among these are collagen and related proteins, which comprise intercellular material of cartilage, dentin, and bone. Ascorbate is also involved in (1) carnitine biosynthesis serving as a cofactor to 6-*N*-trimethyl-L-lysine hydrolase; (2) γ-butyrobetaine hydrolase, which converts γ-butyrobetaine to carnitine; (3) the degradation of tyrosine via 4-OH phenylpyruvate dioxygenase; (4) the synthesis of adrenal hormones via dopamine β-hydroxylase; (5) the biosynthesis of corticosteroids and aldosterone; (6) the hydroxylation of cholesterol in the formation of bile acids; and (7) folate metabolism and leukocyte functions. Nonheme iron absorption, as Fe^{2+}, is also enhanced by simultaneous ingestion of the vitamin.[261]

Ascorbic acid is one of the most effective water-soluble antioxidants in biological fluids[182] and can scavenge physiologically important reactive oxygen species and reactive nitrogen species. Both ascorbate and the ascorbyl radical have low reduction potentials[82] and react with most other biologically relevant radicals. The ascorbyl radical is relatively stable because of resonance stabilization of the unpaired electron. Ascorbate can regenerate other small molecule antioxidants, including α-tocopherol, reduced glutathione, urate, and β-carotene from their respective radical species, and may therefore prevent oxidative damage to biological macromolecules, including DNA, lipids, and proteins. There has been concern that in certain situations of vitamin supplementation ascorbic acid acts as a prooxidant.[444] However, this has been disputed by other workers.[95] It has also been recognized that dehydroascorbate has important intracellular properties that are different from, but sometimes complementary to, those of ascorbate.[130,623]

Requirements and Reference Nutrient Intakes

The amount of vitamin C sufficient to alleviate and cure the clinical signs of scurvy is only 10 mg/day, which is probably near the minimum requirement in man. This amount, however, is not adequate to maintain near saturation of tissue in the adult human male, who has a body pool of 1.5 to 2 g and shows clinical symptoms of deficiency when this total pool falls below about 300 mg.[25,252] Acknowledgment of functions of vitamin C beyond the antiscorbutic, particularly the antioxidant function, has led to the development of the concept of the optimal nutrition state, and the intake required to achieve this. Current recommendations of the U.S. Institute of Medicine about estimated average requirements and RDAs has reflected this approach.[425] The RDA for adult males, older than 19 years and beyond 70 years, has been set at 90 mg/day, and the corresponding RDA for women at 75 mg/day. To provide for fetal needs, an additional 10 mg/day is recommended for the pregnant woman to offset the decrease in plasma vitamin C level during pregnancy. A lactating woman should receive an additional 45 to 50 mg/day, because an average of 18 to 22 mg may be secreted in 600 to 700 mL of milk. Children 1 to 3 years have an RDA of 15 mg/day; those 4 to 8 years, an RDA of 25 mg/day; boys aged 9 to 13, an RDA of 45 mg/day; and those 14 to 18 years, an RDA of 75 mg/day. Corresponding values for girls are 45 and 65 mg/day, respectively. No RDA is given for infants up to 1 year old; instead AI levels of 40 mg/day up to 6 months and 50 mg from 7 to 12 months are recommended. Some special groups, such as smokers, should take an additional 35 mg/day.[353]

Intravenous Supply

The recommended IV intake for adult patients receiving TPN was 100 mg for many years,[9] but this has now been increased to 200 mg/day.[243] This reflects the expected increased requirements for wound healing and for antioxidant activity.

Deficiency

Protracted deficiency of vitamin C leads to the classic disease of scurvy, which still occurs in developed countries. Those most at risk of the disease include (1) elderly men, particularly those who live alone; (2) those with alcohol dependence and smokers; (3) those taking unbalanced diets; (4) some mentally ill patients; (5) renal failure patients undergoing peritoneal dialysis or hemodialysis; and (6) some patients with cancer.[149] The lack of vitamin C causes an inability to form adequate intercellular substance in connective tissue and is reflected in swollen, tender, and often bleeding or bruised loci at joints and in other areas where structurally weakened tissue cannot withstand stress. Infantile scurvy, also known as Barlow's disease, exhibits a bayonet-rib syndrome. The gums are livid and swollen, cutaneous bleeding often begins on the lower thighs as perifollicular hemorrhages, and large spontaneous bruises (ecchymoses) may arise almost anywhere on the body. Ocular hemorrhages, drying of salivary and lacrimal glands, parotid swelling, femoral neuropathy, edema of the lower extremities, and psychological disturbances have also been described. Some scorbutic patients may develop anemia, display radiological changes characteristic of osteoporosis, or die suddenly from heart failure. Diseases of vitamin C deficiency that might reflect its role as an antioxidant include an increased risk of coronary heart disease, as demonstrated in a cohort of Finnish men,[425] and an increased risk of death by stroke in a cohort of elderly British people.[193]

Toxicity

Vitamin C is generally well tolerated by healthy subjects, and ingestion of supplements of 2 to 4 g/day—as taken by some for the prevention or amelioration of the common cold—is usually without hazard, though gastrointestinal irritation has been experienced.[253] Other potential but rare adverse effects include increased oxalate excretion and kidney stone formation, increased uric acid excretion, excess iron absorption, lowered vitamin B_{12} levels, systemic conditioning and "rebound" scurvy, and prooxidant effects in the presence of free Fe^{3+} or Cu^{2+} ions.[172] Ingestion of amounts of vitamin C above 200 mg/day shows little increase in plasma steady-state concentrations and suggests that overload of vitamin C is unlikely. Consideration of such data has led the Food and Nutrition Board of the U.S. Institute of Medicine to propose a tolerable upper intake level for vitamin C to be 2 g/day for adults older than 19 years.[135]

Laboratory Assessment of Status

There are at present no useful functional tests of vitamin C adequacy, thus laboratory assessment of status is made by direct measurement of plasma, urine, or tissue concentrations of ascorbic acid, total vitamin C, or (rarely) metabolite. Because ascorbic acid is readily oxidized by dissolved oxygen at a neutral pH, plasma samples should be treated with a metal-chelating and protein-precipitating acid, such as metaphosphoric acid, soon after a phlebotomy. Samples so treated may be stored at −80 °C for several years.[32] Plasma ascorbate concentration is considered to be a reliable indicator of ascorbate intake[276] and has been measured photometrically by oxidation with 2,4-dinitrophenylhydrazine to form the red *bis*-hydrazone or with 2,4-dichlorophenolindophenol, which is reduced to a colorless form.[548] A more specific approach is to use the enzyme ascorbate oxidase to convert ascorbate to dehydroascorbate, which is then coupled with o-phenylene diamine to form a product that is measured fluorometrically[606] or at 340 nm on an automated analyzer.[325] HPLC methods have the potential advantage of specificity, but are generally more time consuming. Detection may be by precolumn derivatization to the fluorescent quinoxaline, or by electrochemical or coulometric means. Care must be taken during the analysis to prevent oxidation of the ascorbate before detection, because a sulfhydryl donor, such as dithiothreitol or homocysteine, should be added to the sample and mobile phase.[32] With suitable sample preparation, both ascorbic acid and total vitamin C, and by difference, DHA may be measured together by HPLC[360] or gas chromatography–mass spectrometry.[131] Leukocyte ascorbic acid is considered to be a better indicator of body stores than plasma ascorbate, but has not been widely adopted because of the large sample volume requirement, the difficulty of automating the analysis, the influence of fluctuating leukocyte numbers, and the relative difficulty of the analysis. Urinary excretion and RBC concentrations have not been found to be specific and useful indices of vitamin C status; however, urinary levels of ascorbic acid, especially following a load test, can be helpful in the clinical diagnosis of scurvy.

Reference Intervals

With adequate intake of vitamin C, plasma concentrations of total vitamin (ascorbic acid plus dehydroascorbic acid) are between 0.4 and 1.5 mg/dL (23 to 85 µmol/L). The lower limit value may be seen in some cases with subclinical vitamin C deficiency and in older individuals. A value lower than 0.2 mg/dL (11 µmol/L) is considered deficient. The guidance reference interval for vitamin C levels in leukocytes is 20 to 53 $\mu g/10^8$ leukocytes (1.14 to 3.01 fmol/leukocyte). A value in leukocytes of less than 10 $\mu g/10^8$ leukocytes (0.57 fmol/leukocyte) is considered deficient.[548]

BIOTIN

Biotin (also known as vitamin H) is the prosthetic group for a number of carboxylation reactions (e.g., pyruvate, acetyl-CoA, propionyl Co-A, and decarboxylases).

Chemistry

Biotin is *cis*-tetrahydro-2-oxothieno[3,4-*d*]-imidazoline-4-valeric acid (Figure 30-18). The vitamin in most organisms occurs mainly bound to protein. The ε-amino group of the lysyl side chain of protein is linked via an amide function, involving the carboxyl group of the valeryl side chain of biotin. In addition, some biotin is linked noncovalently as a complex with avidin, a protein in egg white.

Dietary Sources

Good sources of biotin include liver, kidney, pancreas, eggs, yeast, and milk. Cereal grains, fruits, most vegetables, and meat are poor sources.[114] The ureido ring and the ionizable carboxyl group of biotin allow modest solubility of the white crystalline solid in aqueous solution, especially at an alkaline pH. Oxidizing agents convert the thioether to sulfoxides and sulfones, which do not have biotin activity.

Absorption, Transport, Metabolism, and Excretion

Biotin in the diet is largely protein bound, and digestion of these proteins by gastrointestinal enzymes produces biotinyl peptides, which may be further hydrolyzed by intestinal biotinidase to release biotin. Avidin, a protein found in raw egg whites, binds biotin tightly and prevents its absorption. The peptide biocytin (ε-N-biotinyl lysine) is resistant to hydrolysis by proteolytic enzymes in the intestinal tract but together with biotin is readily absorbed.[637] A biotin carrier, the sodium-dependent multivitamin transporter (SMVT)

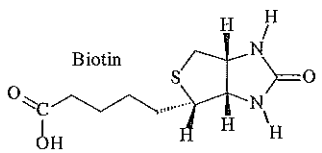

Figure 30-18 Biotin.

for which pantothenic acid and lipoate compete,[449] is located in the intestinal brush border membrane and transports biotin against a sodium ion concentration gradient. The enzyme biocytinase (biotin amidohydrolase) in plasma and erythrocytes catalyzes the hydrolysis of biocytin to yield free biotin. Biotin is cleared from the circulating blood more rapidly in deficient than in normal mammals; it is taken up by such tissues as liver, muscle, and kidney and is localized in cytosolic and mitochondrial carboxylases. Covalent attachment of biotin to apoenzymes involves ATP-dependent conversion of the vitamin to biotinyl-5′-adenylate followed by condensation of the biotinyl moiety with ε-amino groups of specific lysyl residues in apoenzymes preformed from subunits. The enzymes responsible for catalyzing the formation of the ε-N-biotinyl-L-lysyl (biocytinyl) moiety of proteins are holoenzyme synthetases.

About half of the absorbed biotin is excreted as the metabolites bisnorbiotin, occurring from β-oxidation of the valeric acid side chain, and biotin sulfoxide, occurring from the oxidation of the sulfur in the heterocyclic ring.[635] The circulating plasma and urinary excretion patterns show a ratio of 3:2:1 for biotin, bisnorbiotin, and biotin sulfoxide. Minor metabolites are bisnorbiotin methyl ketone and biotin sulfone. Careful balance studies in humans, where perhaps only 1 mg is the total body content, showed that urinary excretion of biotin often exceeded dietary intake, and that in all cases, fecal excretion was as much as three to six times greater than dietary intake because of microfloral biosynthesis.

Functions

The principal biochemical function of biotin in man is as a cofactor for carboxylation reactions. Five carboxylases are currently found in human tissue[487]; one of these, an acetyl-CoA carboxylase, is inactive and may act as a storage vehicle for biotin.[532] The others are carboxylases for acetyl-CoA, propionyl-CoA, β-methylcrotonyl-CoA, and pyruvate. These enzymes operate via a common mechanism, which involves phosphorylation of bicarbonate by ATP to form carbonyl phosphate, followed by transfer of the carboxyl group to the sterically less hindered nitrogen of the biotin moiety. The resulting N(1)-carboxybiotinyl enzyme can then exchange the carboxylate function with a reactive center in a substrate. With cytosolic acetyl-CoA carboxylase, the product is malonyl-CoA, used for fatty acid biosynthesis. In mitochondria, pyruvate carboxylase catalyzes formation of oxaloacetate, which together with acetyl-CoA forms citrate. The other carboxylases are involved in the metabolism of odd-numbered fatty acids and branched-chain fatty acids.[635] Research showing altered gene expression during biotin deficiency and new enzymatic activities of the enzyme biotinidase is confirming earlier suggestions of a role for biotin in the regulation of gene expression.[374]

Requirements and Reference Nutrient Intakes

At present there are insufficient scientific data to make recommendations of RDAs for biotin. Intestinal microflora make a significant contribution to the body pool of available biotin, making determination of the dietary requirement difficult. Mean urinary excretion, reflective of dietary intake, ranges from 6 to 50 μg/day for adults who ingest 28 to 100 μg/day. Consideration of urinary excretion of both biotin and the metabolite 3-hydroxyisovalerate[397] has led to recommendations on AI, rather than requirements.[170] The suggested AI for adults 19 years and older is 30 μg/day; for adolescents 14 to 18 years, 25 μg/day; for children 9 to 13 years, 20 μg/day; for children 4 to 8 years, 12 μg/day; for children 1 to 3 years, 8 μg/day; and for infants less than 1 year, 0.7 μg/kg of body weight. An additional 5 μg/day is recommended for the lactating mother. Those receiving hemodialysis or peritoneal dialysis, or with a biotinidase deficiency, would require more.

Intravenous Supply

The recommended supply of biotin to adults during TPN is 60 μg/day.[9]

Deficiency

Biotin deficiency is uncommon but may be seen (1) with prolonged consumption of raw egg whites, (2) in TPN without biotin supplementation, and (3) in patients with a genetic deficiency of biotinidase. The first two situations may be complicated by effects on gut flora that produce biotin.[487] Symptoms include anorexia, nausea, vomiting, glossitis, pallor, depression, and a dry scaly dermatitis.[91] Based on urinary excretion patterns of 3-hydroxyisovaleric acid, (Figure 30-19) concern has been expressed about marginal biotin deficiency in pregnancy, because this has been shown to be teratogenic in several mammalian species.[396] Significantly lowered urinary excretion or circulating blood levels have also been found in alcoholics, patients with achlorhydria, and among the elderly and some athletes.[61] Finally, there are rather rare genetic enzyme defects, such as in holoenzyme synthetase (reflected in inadequate conversion of apocarboxylases to holocarboxylases) and propionyl-CoA carboxylase (reflected in a distinguishing acidemia).[635]

Toxicity

No adverse effects of biotin in doses of up to 300 times a normal dietary intake have been reported, as in patients with biotinidase deficiency.[624] Tolerable upper intake levels for biotin have not been set, because there are insufficient data.[170]

Laboratory Assessment of Status

Traditionally, biotin has been measured in biological samples by microbiological assay, where whole blood is first digested with papain or acid hydrolysis to release free biotin, samples of which are then added to a biotin-deficient medium inoculated with a test organism, such as *Lactobacillus plantarum*.[502] Other methods for unbound biotin include avidin-binding assays, where a competitive protein-binding radioassay is set up with ^{3}H-labeled biotin, or a nonradioactive enzyme-linked sorbent assay using streptavidin as the

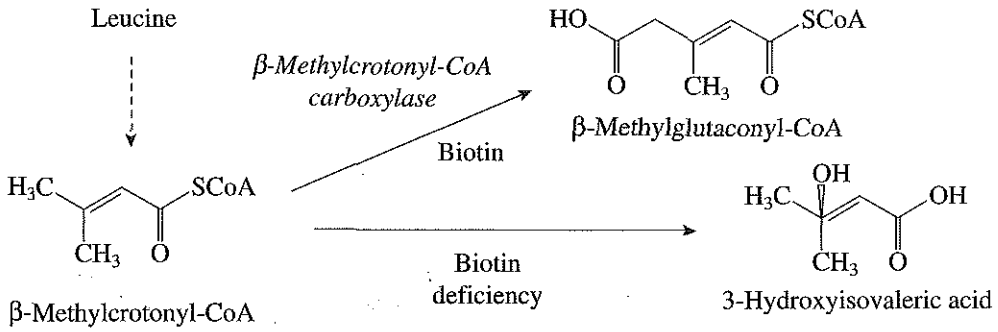

Figure 30-19 Formation of 3-hydroxyisovaleric acid under conditions of biotin deficiency.

binding agent.[502,614] Generally, biotin content of red cells is similar to that of plasma for a given method, but there is often poor agreement between methods, which may relate to the specificity of the methods employed.[495] Urinary excretion of biotin and 3-hydroxyisovaleric acid appears to be a better indicator of biotin status than blood concentrations. This was shown in a study of experimental biotin deficiency, when both urinary biotin and metabolites, measured by HPLC separation followed by an avidin-binding assay, and urinary 3-hydroxyisovaleric acid, measured by gas chromatography–mass spectrometry, showed significant changes whereas serum biotin concentration did not.[397] Functional markers of biotin status are being increasingly investigated. Lymphocyte propionyl-CoA carboxylase, measured by an optimized assay that is based on the incorporation of labeled $H^{14}CO_3^-$, has been shown to be an early and sensitive indicator of biotin deficiency in a rat model,[395] in patients on prolonged TPN without biotin,[598] and in children with protein-energy malnutrition.[597]

Reference Intervals

Typical reference interval values for whole blood biotin by a microbiological method are 0.5 to 2.20 nmol/L, mean 1.31 nmol/L. Deficiency is considered likely below 0.5 nmol/L.[502] Reference values for other metabolites and fluids have been published elsewhere.[495]

Folic Acid

Folic acid serves as a carrier of one-carbon groups in many metabolic reactions. It is required for the biosynthesis of compounds such as choline, serine, glycine, purines, and deoxythymidine monophosphate (dTMP).

Chemistry

Folate and *folic acid* are generic terms for a family of compounds that function as coenzymes in the processing of one-carbon units and that are derived from pteroic acid (*Pte*), to which one or more molecules of glutamic acid are attached. Pteroic acid is composed of a pteridine ring joined to a *p*-aminobenzoic acid residue (Figure 30-20). In basic solution, this substance has absorption maxima at 256, 282, and 365 nm and is fluorescent. When pteroic acid is conjugated with one molecule of L-glutamic acid, pteroylglutamic acid (PteGlu) is formed, and this can be reduced to dihydrofolic acid (H_2PteGlu or DHF/FH_2,) with hydrogens in positions 7 and 8, or to tetrahydrofolate (H_4PteGlu or THF/FH_4) with hydrogens in positions 5, 6, 7, and 8. Only the reduced forms are biologically active. Other folate derivatives have multiple glutamic acid residues (H_4PteGlu$_n$), when *n*, the number of glutamate residues, may be 1 to 7. Biochemically, these polyglutamates are similar to monoglutamates, but the former function as the natural coenzymes. Multiple forms of folic acid occur with substitutions of functional groups, such as methyl, formyl, methylene, hydroxymethyl, and others at nitrogen atoms in the pteroic acid residue, usually N^5 or bridging N^5 and N^{10}. Although various forms of folic acid are normally present in human serum and other body fluids, the principal form is 5-methyltetrahydrofolate. This is slowly oxidized in alkaline solution, but this is reversed by adding ascorbic acid. It is relatively stable in acid solutions but unstable when exposed to light.

Dietary Sources

The principal food sources of folate are liver, spinach, and other dark green leafy vegetables, legumes, such as kidney and lima beans, and orange juice, although in countries where cereal fortification with folate is established, this is often the major source of dietary folate.[21,549] Since the U.S. FDA program of fortification of all enriched grain products with folic acid (140 µg per 100 g) began in 1996, study populations have shown a doubling of mean plasma folate concentrations and significant falls in total homocysteine concentration, though data are not available as yet to show if the incidence of neural tube defects (NTDs), the primary purpose of the fortification, has been reduced.[279]

Absorption, Transport, Metabolism, and Excretion

Folate is absorbed from dietary sources, such as those listed above, mainly as reduced methyl- and formyl-tetrahydropteroylpolyglutamates. The bioavailability of folate from food sources is variable and dependent upon factors such as incomplete release from plant cellular structure, entrapment in food matrix during digestion, inhibition of deglutamation by other dietary constituents, and possibly the degree of

polyglutamation.[211,491] The bioavailability of supplemental folic acid is greater than that of food folate, and may be as high as 100% for folic acid supplements taken on an empty stomach compared with about 50% for food folates.[170] Polyglutamate forms of folate present in food are first converted to monoglutamates, by pteroylpolyglutamate hydrolase, in the intestinal mucosa. Absorption of the monoglutamyl folates at low concentration occurs by a saturable transport process with an acidic pH optimum (pH around 5), with an additional apparently nonsaturable absorption mechanism when intestinal folate concentrations exceed 5 to 10 μmol/L.[363] After cellular uptake, most of the folate is reduced and methylated and enters the circulation as 5-methyltetrahydrofolate (5-MTHF), circulating loosely bound to albumin or to a lesser degree to a high-affinity folate-binding protein. Uptake by certain cells (kidney, placenta, and choroid plexus) occurs by membrane-associated folate-binding proteins that act as folate receptors, and the reduced folate carrier, a member of the SLC19 family, facilitates uptake by most tissue.[365] Once within the cell, 5-MTHF is demethylated and converted to the polyglutamyl form by folylpolyglutamate synthase, which helps to retain folate within the cell, because it is unable to cross cell membranes. For release into the circulation, the polyglutamates are reconverted to monoglutamates by polyglutamate hydrolase.

Folic acid and vitamin B_{12} metabolism are linked by the reaction that transfers a methyl group from 5-MTHF to cobalamin. In cases of cobalamin deficiency, folate is "trapped" as 5-MTHF and is "metabolically dead." It cannot be recycled as tetrahydrofolate (THF) back into the folate pool to serve as the main one-carbon unit acceptor for many biochemical reactions. Eventually, cellular depletion of MTHF ensues, causing a reduction in thymidylic acid synthesis, which in turn results in megaloblastic anemia and neuropathies. This concept is supported by the fact that THF corrects the megaloblastic anemia in patients with congenital methylmalonic aciduria and homocystinuria, whereas it is not corrected with methyltetrahydrofolate. However, some investigators have suggested that vitamin B_{12} is required for the conversion of folic acid to the formyl form and that formyltetrahydrofolates are the natural substrates for forming folate polyglutamates.

Protein-free plasma folate is filtered at the glomerulus and most is reabsorbed by the proximal renal tubules. Consequently, intact urinary folate is only a small percentage of intake. Folate is predominantly excreted by catabolism following cleavage of the C9-N10 bond to produce *p*-aminobenzoylpolyglutamates, which are then hydrolyzed to monoglutamates and *N*-acetylated before excretion. Biliary excretion of folate has been estimated at about 100 μg/day, but much of this is reabsorbed in an enterohepatic circulation. Fecal losses have been studied by radiolabeling and have been found to be similar in type and quantity to urinary losses.[315]

Functions

Folate coenzymes, together with coenzymes derived from vitamins B_{12}, B_6, and B_2, are essential for one-carbon metabolism. Biochemically, a carbon unit from serine or glycine is

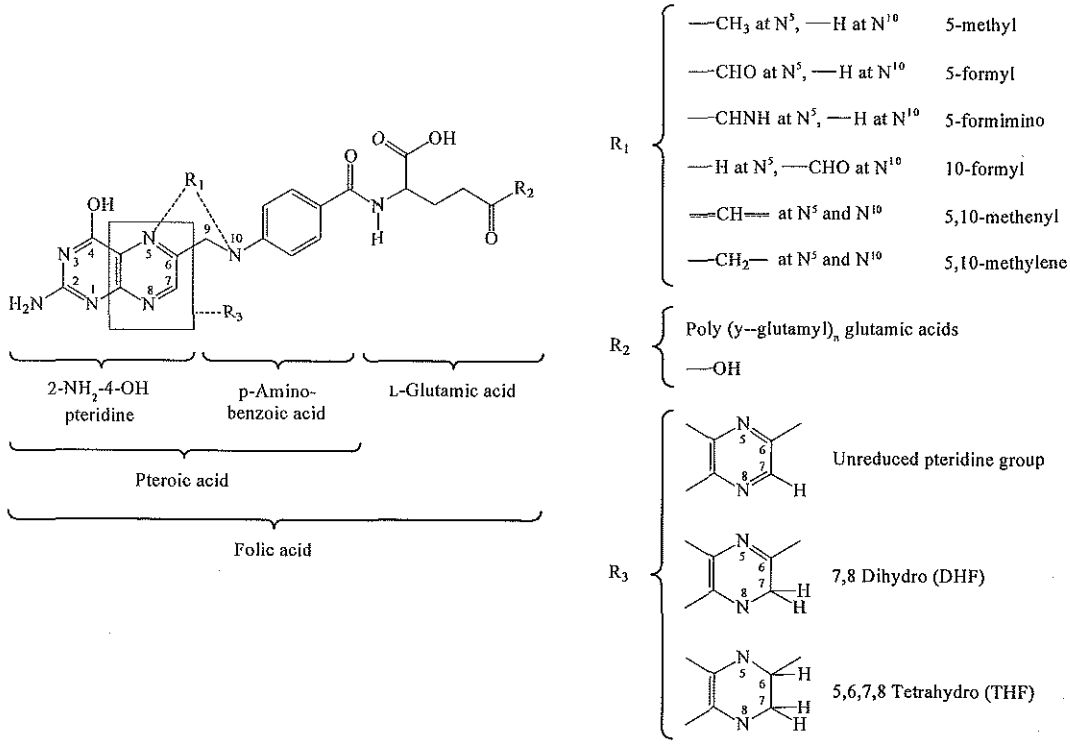

Figure 30-20 Structure and relationships of folic acid and its derivatives.

transferred to THF to form methylene-THF, which is then (1) used in the synthesis of thymidine (and incorporation into DNA), (2) oxidized to formyl-THF for use in the synthesis of purines (precursors of RNA and DNA), or (3) reduced to methyl-THF, which is necessary for the methylation of homocysteine to methionine. Much of this methionine is converted to S-adenosylmethionine, a universal donor of methyl groups to DNA, RNA, hormones, neurotransmitters, membrane lipids, and proteins.[512] Some of these reactions are illustrated in Figure 30-21. Different folates are involved in these reactions, depending on the chemical state of the single carbon fragments transferred:

Reaction	Group Transferred	Folic Acid Derivative
Serum/glycine metabolism	Methylene ($-CH_2-$)	N^5, N^{10}-Methylene THF/FH_4
Histidine catabolism	Formimino ($-CHNH$)	N^5-Formimino THF/FH_4
Thymidylate synthesis	Methylene ($-CH_2-$)	N^5, N^{10}-Methylene THF/FH_4
Methionine synthesis	Methyl ($-CH_3$)	N^5-Methyl THF/FH_4
Purine synthesis	Methenyl ($=CH-$)	N^5, N^{10}-Methenyl THF/FH_4
	Formyl ($-CHO$)	N^{10}-Formyl THF/FH_4

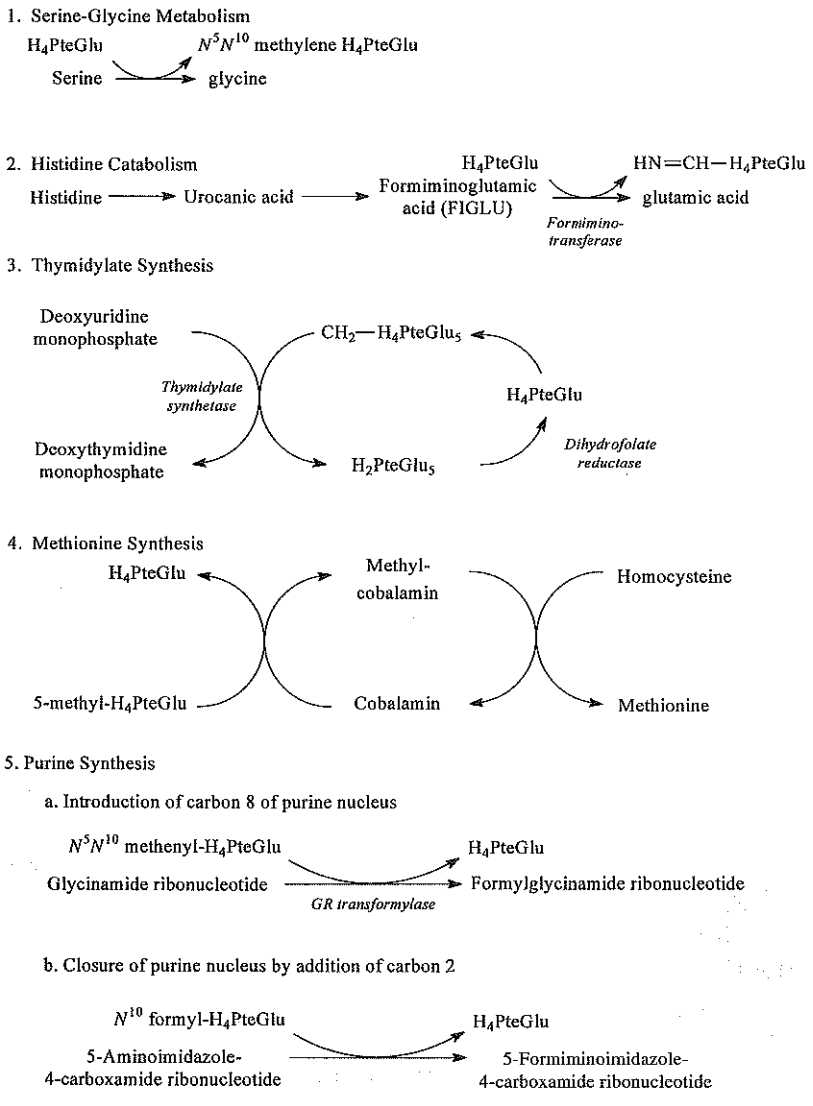

Figure 30-21 The 5 major metabolic functions of folate in human cells.

The interconversion of these forms of folic acid takes place through various electron transfer reactions facilitated by specific enzyme systems and coenzymes, such as the reduced forms of flavin-adenine dinucleotide ($FADH_2$) and NADPH. The conversion between the N^5-, N^{10}-methylene form and N^{10}-formyl forms is readily reversible, but the reduction of methylene to methyl and reduction of free THF to formyltetrahydrofolate is essentially irreversible. Conversion of N^5-methyltetrahydrofolate back to free THF may require cobalamin.

The role of folic acid in the metabolism of homocysteine has received increased interest recently.[631] Elevations of plasma homocysteine concentrations have been shown to be independent risk factors for coronary artery disease[460,583] and probably cerebrovascular disease (see Chapter 26).[399] The involvement of folate in its coenzyme forms with homocysteine and methionine metabolism is summarized in Figure 30-22. Folate is the principal micronutrient determinant of homocysteine status,[323] and supplementation with folate has been used as a treatment modality to reduce circulating homocysteine concentrations. Primary (fasting) homocystinemia can be treated with 0.5 to 5.0 mg/day of folic acid,[592] with an expectation of an approximate 25% fall in baseline concentration.[205]

Requirements and Reference Nutrient Intakes

Based on folate concentrations in liver biopsy samples, and assuming that the liver contains about half of all body stores, total body stores of folate are estimated to be between 12 and 28 mg.[618] Kinetic studies that show both fast-turnover and very-slow-turnover folate pools indicate that about 0.5% to 1% of body stores are catabolized or excreted daily,[212] suggesting a minimum daily requirement of between 60 and 280 μg to replace losses. In calculating nutritional requirement, the concept of dietary folate equivalents (DFE) has been used to adjust for the nearly 50% lower bioavailability of food folate compared with supplemental folic acid, such that 1 μg DFE = 0.6 μg of folic acid from fortified food = 1 μg of food folate = 0.5 μg folic acid supplement taken on an empty stomach.[170] Before the fortification program of cereal grains with folic acid conducted between 1988 and 1994, the median intake of folate from food in the United States was approximately 250 μg/day; this figure is expected to increase by about 100 μg/day after fortification. Recommendations

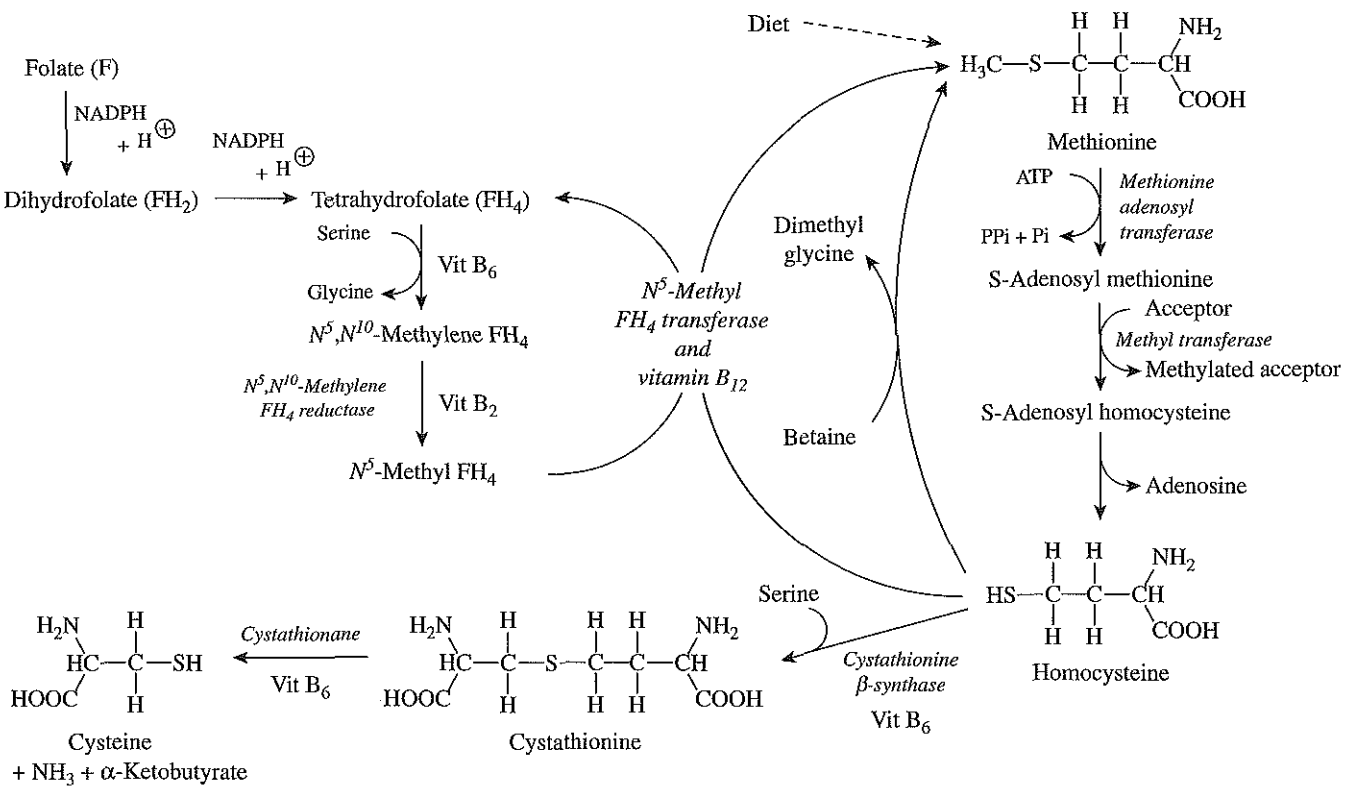

Figure 30-22 Metabolism of homocysteine and methionine.

on dietary reference intakes by the U.S. Institute of Medicine made in 1998 have shifted the emphasis away from prevention of deficiency and toward the concept of optimal health.[170] There is also an increased awareness of the contribution of micronutrient intake to genomic stability.[155] Current RDAs of the U.S. Institute of Medicine are 400 µg/day DFE for adults 19 years and older, and also for adolescents between 14 and 18 years; 300 µg/day DFE for children 9 to 13 years; 200 µg/day DFE for children 4 to 8 years; and 150 µg/day DFE for children 1 to 3 years. An adequate intake for infants of 0 to 6 months is set at 65 µg/day DFE and at 80 µg/day DFE for infants 7 to 11 months. Based on maintenance of erythrocyte folate concentrations during pregnancy, the RDA for pregnant women of all ages is set at 600 µg/day DFE, and at 500 µg/day DFE for lactating women of all ages.[22,170]

Intravenous Supply

The previous adult recommendation for intravenous supply of folic acid of 400 µg/day has been increased to 600 µg/day, as part of the requirements set by the FDA.[243]

Deficiency

Deficiency of folate may result from (1) the absence of intestinal microorganisms (gut sterilization), (2) poor intestinal absorption (e.g., after surgical resection or in celiac disease or sprue), (3) insufficient dietary intake (including chronic alcoholism), (4) excessive demands (as in pregnancy, liver disease, and malignancies), (5) administration of antifolate drugs (e.g., methotrexate), and (6) anticonvulsant therapy (that can increase folate requirements, especially during pregnancy).[334] Inadequate folate intake leads first to decreased serum folate concentration, then a decrease in erythrocyte folate concentration, an increase in plasma homocysteine, and then megaloblastic changes in the bone marrow and other tissue.[170] Megaloblastic anemia (characterized by large, abnormally nucleated erythrocytes in the bone marrow) is the major clinical manifestation of folate deficiency, although sensory loss and neuropsychiatric changes may also occur. Deficiency of folate and iron may coexist in malnourished people, in which case the macrocytosis of RBCs, otherwise typical of folic acid deficiency, is not observed.

Pregnancy brings increased demand upon folate stores because of increased DNA synthesis and one-carbon transfer reactions and low serum folate concentrations in pregnancy are associated with adverse outcomes, including preterm delivery, infant low birth weight, and fetal growth retardation.[501] Additionally, many observational studies have confirmed a reduction in risk of NTDs with periconceptual folic acid supplementation.[65] In a large controlled intervention trial conducted in two regions of China and involving approximately 250,000 women, a daily supplement of 400 µg of folic acid taken at least 80% of the time was associated with an 85% risk reduction of NTDs in an area of high baseline frequency and a 40% reduction in an area of low baseline frequency.[49] Current suggestions are that women planning pregnancy should take at least 400 µg/day, although an intake of 5 mg of folic acid daily is recommended, especially for those with a previous history of NTD.[608] Although the etiology of NTDs is probably multifactorial, involving more than one aspect of folate use,[29] one factor that contributes to this and other folate-requiring conditions is genetic polymorphism.

The most extensively studied polymorphic alleles are those of 5,10-methylenetetrahydofolate reductase (MTHFR), the enzyme responsible for the irreversible reduction of 5,10-MTHF to 5-methyltetrahydrofolate (5-MTHF), the methyl donor of homocysteine to methionine. A single point C to T mutation at base pair 677 (C677T), causing a substitution of valine for alanine, leads to a thermolabile protein with reduced enzymatic activity. The homozygous T/T enzyme has an incidence of around 12% in Asian and Caucasian populations, and a loss of enzyme activity of about 50%, and the heterozygous C/T variant can have an incidence of up to 50% in some populations, with a lesser degree of enzyme inactivity.[69,294]

This variant, and a second with an A to C substitution at base pair 1298 (A1298C), with its effects on folate metabolism and intracellular folate availability, may increase the risk of chromosomal aberrations, and its link with leukemia has been reviewed.[472] A further enzyme involved in folate metabolism, methionine synthase, has also been shown to have at least two relatively prevalent polymorphisms, though these are thought to be benign.[105] The absorption of folate from polyglutamyl folate food sources is thought to be reduced by a variant of glutamate carboxypeptidase II because of a H475Y substitution.[132]

Lower than normal serum folate concentrations have been reported in patients with psychiatric disorders. In two studies, about one third of psychiatric patients had low RBC folate levels, with most of the low values being in depressed patients. Another study reported an inverse correlation between serum folate levels and the duration of depressive illness. Limited evidence suggests that folate may have a role as a supplement to other treatments for depression.[566]

Toxicity

No adverse effects have been reported from the consumption of folate-fortified foods, thus any signs of toxicity are associated with supplemental folate. Most of the limited evidence suggests that excessive folate supplementation, typically in doses up to 10 mg/day, though some have gone to 500 mg/day, can precipitate or exacerbate neuropathy in vitamin B_{12}–deficient subjects, and it is this endpoint that has been used to set a tolerable upper intake level of 1 mg/day from fortified food or supplements for adults.[170] One recognized complication of folate supplementation is to "mask" vitamin B_{12} deficiency, because the associated anemia responds to folate alone. This may delay treatment of the deficiency, allowing neurological abnormalities to progress.

Laboratory Assessment of Status

Folate status may be reliably assessed by direct measurement of serum and erythrocyte or whole blood concentrations, and its metabolic function as coenzyme assessed by metabolite concentrations, such as plasma homocysteine (see Chapters 20 and 26). Serum folate concentrations are considered indicative of recent intake and not of tissue stores, but serial measurements have been used to confirm adequate intake. Whole blood or erythrocyte folate concentrations are more indicative of tissue stores and have been shown to have a moderate correlation with liver folate concentrations taken through a biopsy.[170] Because folate is taken up only by the developing erythrocyte in the bone marrow and not by the mature cell, erythrocyte concentrations reflect folate status over the 120-day lifespan of the cell. Urine folate excretion is not considered to be a sensitive indicator of folate status.[495]

CPB assays have now largely replaced microbiological procedures for the measurement of serum, whole blood, or erythrocyte folate, though the use of microtiter 96-well plates has enabled microbiological assay using *Lactobacillus casei* to be partly automated.[427] The binder used in the CPB folate assay is a protein that occurs naturally in milk, called β-lactoglobulin or milk folate binder, commonly used together with a radioactive ^{125}I-folate label, though nonisotopic fluorescence and bioluminescence labels are becoming more popular. One commercial assay uses selective protein binding coupled to ion capture, followed by fluorescence assay. However, because problems of standardization and intermethod agreement persist with CPB assays, more specific analytical techniques have been developed, including HPLC with electrochemical or mass-spectrometric detection.[32]

Several analytes are known to be indicative of folate metabolism. Plasma total homocysteine increases when there is a deficiency of 5-MTHF, such that the methylation of homocysteine to methionine is compromised. However, though plasma homocysteine is considered to be a sensitive functional indicator, it is not specific because its concentration can be influenced by deficiency of other vitamins (B_6 and B_{12}) involved in the metabolism of homocysteine. Similarly the methylation of DNA is dependent upon adequate 5-MTHF. A sensitive new method for the rapid detection of abnormal methylation patterns in global DNA patterns has been reported and may have promise as a functional marker,[445] as may the measurement of the degree of uracil incorporation into DNA, 5,10-methylene THF being required for the conversion of deoxyuridine monophosphate (dUMP) to dTMP by thymidylate synthetase.[60]

Reference Intervals

Because of methodological differences, reference values for folate are method dependent. The data collected from the NHANES of 1988 to 1994 in the United States, in which almost 3000 blood samples were analyzed, produced reference intervals of 2.6 to 12.2 μg/L (6.0 to 28.0 nmol/L) for serum folate and 103 to 411 μg/L (237 to 945 nmol/L) for erythrocyte folate. Biochemical deficiency has been defined as a concentration of <1.4 μg/L (<3.2 nmol/L) for serum folate and <110 μg/L (<253 nmol/L) for erythrocyte folate.[+]

Niacin and Niacinamide

Niacin and niacinamide (nicotinamide and nicotinic acid amide) are converted to the ubiquitous redox coenzymes nicotinamide-adenine dinucleotide $(NAD)^+$ and nicotinamide-adenine dinucleotide phosphate $(NADP)^+$.

Chemistry

The term niacin refers to nicotinic acid (pyridine-3-carboxylic acid), its amide nicotinamide, and derivatives that show the same biological activity as nicotinamide. A distinction between the two primary vitamin forms has to be considered, however, when considering some aspects of their metabolism and especially their different pharmacological actions at high doses. Structures of both vitamers and the two coenzyme forms containing the nicotinamide moiety are given in Figure 30-23.

Dietary Sources

Nicotinamide-adenine dinucleotide (NAD; diphosphopyridine nucleotide) and nicotinamide-adenine dinucleotide phosphate (NADP; also termed triphosphopyridine nucleotide) represent most of the niacin activity found in good sources that include yeast, lean meats, liver, and poultry.[101] Milk, canned salmon, and several leafy green vegetables contribute lesser amounts but are still sufficient to prevent deficiency. Additionally, some plant foodstuffs, especially cereals such as corn and wheat, contain niacin bound to various peptides and sugars in forms nutritionally not readily available (niacinogens or niacytin).[274] Because tryptophan is a precursor of niacin, protein provides a considerable portion of niacin equivalent. As much as two thirds of niacin required by adults can be derived from tryptophan metabolism via nicotinic acid ribonucleotide

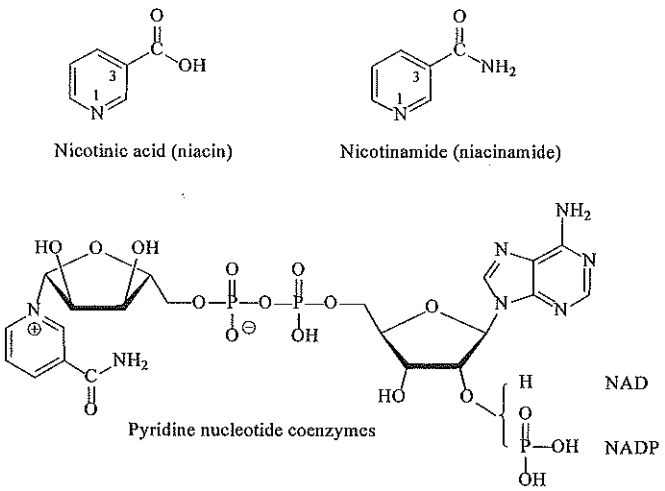

Figure 30-23 Niacin, niacinamide, and coenzyme.

to NAD and NADP. It has been found that 60 mg of tryptophan can provide the equivalent of 1 mg of niacin in the adult. In countries where fortification of processed cereals is practiced, this may provide up to 20% of niacin intake.[274]

Free forms of the vitamin are white, stable solids that are quite soluble in water. The oxidized coenzymes are labile to alkali, whereas the reduced (dihydro) coenzymes are labile to acid. Reduction of the oxidized coenzymes commonly occurs by addition of a hydride ion to the *para* (4) position of the nicotinamide ring, with simultaneous formation of a solvated proton. NADH and NADPH (but not NAD and NADP) absorb light in the near ultraviolet region (339 nm). This forms the basis for many biochemical assays.

Absorption, Transport, Metabolism, and Excretion

Dietary NAD and NADP are hydrolyzed by enzymes, such as NAD glycohydrolase, in the intestinal mucosa to release nicotinamide, which together with any nicotinic acid is rapidly absorbed in both the stomach and intestine by an Na^+-dependent facilitated diffusion at low concentrations and passive diffusion at higher concentrations.[35] Nicotinamide is the main circulating form in the plasma, either postabsorption or by release from hydrolyzed liver NAD, and this can be taken up by most tissue requiring NAD by simple diffusion, though there is evidence of a facilitated transport in the erythrocyte.[319]

Once inside blood, kidney, brain, and liver cells both nicotinic acid and nicotinamide are converted to the coenzyme forms. The first step involves the cytosolic phosphoribosyltransferase-catalyzed reaction of nicotinate or nicotinamide with 5-phosphoribosyl-1-pyrophosphate to form pyrophosphate and nicotinic acid ribonucleotide or nicotinamide ribonucleotide, respectively.[367] An additional source of nicotinic acid ribonucleotide is from the action of quinolate phosphoribosyltransferase on quinolinate formed from tryptophan. The efficiency of this pathway is under nutritional and hormonal regulation, with deficiency of vitamin B_6 (riboflavin) and iron slowing the conversion—and protein, tryptophan, energy, and niacin restriction increasing the efficiency.[274] Nicotinic acid ribonucleotide from whatever source is converted to deamido-NAD by an adenylyltransferase catalyzed attachment of the AMP moiety from ATP, and the deamido compound subsequently reacts with glutamine and a cytosolic ATP–dependent synthetase step to yield NAD, glutamate, and phosphate. Nicotinamide mononucleotide is directly converted by the adenylyltransferase to NAD. NADP is formed by a kinase-catalyzed phosphorylation of NAD. In the tissue, most of the vitamin is present as nicotinamide in NAD and NADP, although the liver may contain a significant fraction of the free vitamin. There is little storage of niacin as such.

Excess niacin is excreted mainly as the N-methylnicotinamide (NMN), after methylation in the liver, and the two oxidation products of NMN, N-methyl-2-pyridone-5-carboxamide, and N-methyl-4-pyridone-carboxamide.[402]

Functions

Niacin is essential as the coenzymes NAD and NADP in which nicotinamide acts as an electron acceptor or hydrogen donor in a large number of redox reactions. Many of the enzymes function as dehydrogenases and catalyze such diverse reactions as the conversion of alcohols (often sugars and polyols) to aldehydes or ketones, hemiacetals to lactones, aldehydes to acids, and certain amino acids to keto acids.[367] The common mechanism of operation involves the stereospecific abstraction of a hydride ion from substrate, with *para* addition to one or the other side of carbon 4 in the pyridine ring of the nucleotide coenzyme. The second hydrogen of the substrate group oxidized is concomitantly removed as a proton and ultimately exchanges as a hydronium ion. Most dehydrogenases using NAD or NADP function reversibly. Glutamate dehydrogenase, for example, favors the oxidative direction, whereas others, such as glutathione reductase, preferentially catalyze reduction. In addition to redox reactions, NAD is also a substrate for three classes of enzymes that cleave the β-N-glycosylic bond of NAD to free nicotinamide and catalyze the transfer of adenosine diphosphate (ADP)-ribose.[321] One such enzyme, poly(ADP-ribose) polymerase-1 (PARP-1), is involved in base excision repair and is thought to be important for genomic stability.[219] Nicotinic acid, when used as a pharmaceutical agent, has important antiatherogenic properties. It effectively lowers triglycerides, raises HDL cholesterol, and shifts LDL particles to a less atherogenic phenotype.[270]

Requirements and Reference Nutrient Intakes

Requirements for niacin are expressed as niacin equivalents (NE), which take account of the contribution of tryptophan derived from protein. Earlier estimates of niacin requirements were based on energy expenditure, reflecting the biological function of the niacin coenzymes in the oxidation of fuel molecules. However, current recommendations merely reflect the fact that different age groups and sexes have, on average, different energy expenditure and that no directly relevant studies have linked energy intake or expenditure with niacin requirement.[170] The median intake of preformed niacin from food in the United States is 28 mg for men and 18 mg for women. A study of two Canadian populations showed corresponding values of 41 mg and 28 mg per day. Additionally the average U.S. diet supplies between 0.7 and 1.1 g of tryptophan per day.[410] Based on niacin metabolite excretion data, current RDA for males 19 years to more than 70 years are 16 mg/day of NE, and for women of the same age, 14 mg/day. An increase of 4 NE per day during pregnancy is recommended and an increase of 3 NE daily for lactation will offset the preformed niacin lost in milk. Human milk contains approximately 0.17 mg of niacin and 22 mg of tryptophan/dL or 70 kcal, and these amounts are adequate to meet niacin needs of the infant. Adequate intakes of 2 mg/day of preformed niacin and 4 mg/day NE have been extrapolated from adult requirements for infants of 0 to 6 months and 7 to 12 months, respectively. RDAs are set at

6 mg/day for children 1 to 3 years, 8 mg/day for children 4 to 8 years, 12 mg/day for boys and girls 9 to 13 years, 14 mg/day for girls 14 to 18 years, and 16 mg/day for boys 14 to 18 years.[170]

Intravenous Supply

The recommended supply to adult patients receiving TPN is 40 mg/day in the form of nicotinamide.[9] This increase above the oral recommendations will ensure an adequate intake to match increased energy expenditure.

Deficiency

Pellagra is the classic deficiency disease of the human that has been most often found among those who subsist chiefly on corn (maize), which is low in both niacin and tryptophan.[474] Although its pathogenesis has been attributed to a deficiency of these two factors, other associated complicating factors are a lack of pyridoxal-5-phosphate, FAD, and iron, which are functional in the conversion of tryptophan to niacin and the presence of mycotoxins elaborated by mold infestations, mainly by *Fusarium*.[622] Pellagra is also an occasional secondary manifestation of *carcinoid syndrome,* in which up to 60% of tryptophan is catabolized to 5-OH tryptophan and serotonin; *Hartnup disease,* an autosomal recessive disorder in which several amino acids, including tryptophan, are poorly absorbed; and in treatment with the antituberculous drug isoniazid, which competes with pyridoxal-5-phosphate.

The typical presentation of pellagra is that of a chronic wasting disease associated with dermatitis, dementia, and diarrhea. The characteristic erythematous dermatitis is bilateral and symmetrical and occurs on skin areas exposed to sunlight. Mental changes include fatigue, insomnia, and apathy, which precede an encephalopathy characterized by confusion, disorientation, hallucination, loss of memory, and eventually frank organic psychoses. The diarrhea, when it occurs, reflects a widespread inflammation of the intestinal mucous surfaces, including a bright red tongue; other gastrointestinal manifestations include achlorhydria, glossitis, stomatitis, and vaginitis.

Toxicity

Although no toxic effects have been associated with niacin intake from naturally occurring foods, the use of supplements and pharmacological doses of niacin has produced adverse effects in some subjects. In disorders of reduced tryptophan availability, such as Hartnup syndrome and carcinoid syndrome, daily niacin doses of 40 to 200 mg may be required, and in the treatment of dyslipidemias nicotinic acid in doses up to 6 g daily may be used. Such doses are commonly associated with vascular dilation or "flushing," a burning, tingling sensation of the face (that may be reddened), arms, and chest, and is thought to be mediated by prostaglandins. This may be modulated by gradual increments of the drug and by taking with meals. Other side effects of high-dose niacin treatment are pruritus, nausea, vomiting, and diarrhea, though these symptoms often abate with continued therapy. Additional effects are abnormal glucose tolerance, hyperuricemia, peptic ulcer, hepatomegaly, jaundice, and increased serum aminotransferases. In a study of 814 patients on a combination extended-release niacin preparation (maximum dose, 2 g), flushing caused intolerance in 10% of those studied, hepatotoxicity was seen in 0.5%, and myopathy was not reported.[398] The symptoms of flushing have been taken as an end point sign in the formulation of a tolerable upper intake level for niacin. This has been set at 35 mg/day for adults of 19 years and older, with lower levels for children and adolescents.[170]

Laboratory Assessment of Status

At present, no blood markers are commonly used as indicators of niacin status. Most assessments of niacin nutriture have been based on measurement of the 2 urinary metabolites, N′-methylnicotinamide and N′-methyl-2-pyridone-5-carboxamide. Normally, adults excrete 20% to 30% of their niacin in the form of methylnicotinamide and 40% to 60% as the pyridone. An excretion ratio of pyridone to methylnicotinamide of 1.3 to 4.0 is thus normal, but latent niacin deficiency is indicated by a value below 1.0. As depletion occurs, the pyridone is absent for weeks before clinical signs are noted, and the methylnicotinamide excretion falls to a minimum at about the time that clinical signs are evident.[495] HPLC methods are currently the methods of choice,[492,529] though some capillary electrophoresis methods have been developed.[272] However, the measurement of 2-pyridone and N′-methylnicotinamide concentrations in plasma may provide a more reliable metabolite ratio than urine measurements. A newer approach that may prove valuable is the ratio of NAD/NADP in erythrocytes and plasma tryptophan. A ratio of NAD/NADP below 1.0 would be indicative of a risk of developing niacin deficiency.[188]

Reference Intervals

A guidance reference interval for the excretion rate of N^1-methylnicotinamide is 2.4 to 6.4 mg/day (17.5 to 46.7 μmol/day) or 1.6 to 4.3 mg/g creatinine (11.7 to 31.4 μmol/g creatinine).[277,495]

Pantothenic Acid

Pantothenic acid is a component of coenzyme A (CoA) and is required for the metabolism of fat, protein, and carbohydrate via the citric acid cycle.

Chemistry

Pantothenic acid is of ubiquitous occurrence in nature, where it is synthesized by most microorganisms and plants from pantoic acid (D-2,4-dihydroxy-3,3-dimethylbutyric acid) derived from L-valine, and β-alanine derived from L-aspartate. Addition of cysteamine at the C-terminal end and phosphorylation at C4 of pantoic acid forms 4′-phosphopantetheine, which serves as a covalently attached prosthetic group of acyl carrier proteins, and, when attached

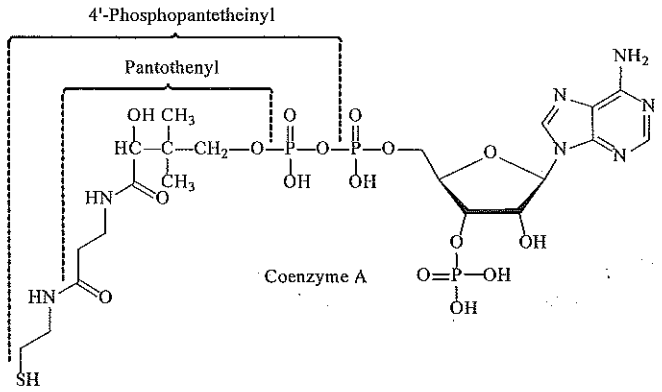

Figure 30-24 Pantothenate and 4′-phosphopantetheine as components of CoA.

to ribose 3′-phosphate and adenine, CoA as shown in Figure 30-24. Pantothenic acid is a hygroscopic, viscous oil, which is easily destroyed by heat, especially at extremes of pH. The most common commercial synthetic form is the calcium salt.

Dietary Sources

Pantothenic acid is widely distributed in foods, mostly within CoA-containing compounds, and is particularly abundant in animal sources, legumes, and whole grain cereals. Excellent food sources (100 to 200 μg/g dry weight) include egg yolk, kidney, liver, and yeast. Fair sources (35 to 100 μg/g) include broccoli, lean beef, skimmed milk, sweet potatoes, and molasses. More than one half of the pantothenate in wheat may be lost during manufacture of flour, and up to one third is lost during cooking of meat.[170,443]

Absorption, Transport, Metabolism, and Excretion

Pantothenic acid is taken in as dietary CoA compounds and 4′-phosphopantetheine and hydrolyzed by pyrophosphatase and phosphatase in the intestinal lumen to dephospho-CoA, phosphopantetheine, and pantetheine. This is further hydrolyzed to pantethenic acid. The vitamin is primarily absorbed as pantothenic acid by a saturable process at low concentrations and by simple diffusion at higher ones. The saturable process is facilitated by a sodium-dependent multivitamin transporter, for which biotin and lipoate compete.[449] After absorption, pantothenic acid enters the circulation and is taken up by cells in a manner similar to its intestinal adsorption. The synthesis of CoA from pantothenate is regulated by pantothenate kinase, which itself is subject to negative feedback from the products CoA and acyl-CoA.[553] The steps involved were outlined above. Pantothenic acid is excreted in the urine after hydrolysis of CoA compounds by enzymes that cleave phosphate and the cysteamine moieties. Only a small fraction of pantothenate is secreted into milk and even less into colostrum.

Functions

Pantothenic acid has two major metabolic roles, the first as part of CoA and the other as the prosthetic group of the acyl-carrier protein (ACP). In the former role, CoA is primarily involved in acetyl and acyl transfer reactions in catabolic processes of carbohydrate, lipid, and protein chemistry. Examples of these are the acetylation of sugars, phospholipid, isoprenoid, and steroid biosynthesis and protein acetylation.[388] Acetyl-CoA that derives from the metabolism of carbohydrates, fats, and amino acids can acetylate compounds, such as choline and hexosamines to produce essential biochemicals; it can also condense with other metabolites, such as oxaloacetate, to supply citrate and cholesterol. As the 4′-phosphopantetheine moiety of ACP, the phosphodiester-linked prosthetic group uses the sulfhydryl terminus to exchange with malonyl-CoA to form an ACP-S malonyl thioester, which can chain elongate during fatty acid biosynthesis.[368] In a 1998 study, pantothenic acid was found to protect rats against some deleterious effects of gamma radiation.[534] In a 2001 study, it was found to have antioxidant properties, thereby protecting lymphocytes against ultraviolet light–induced apoptosis.[535] Pantothenic acid used pharmaceutically may have benefits of lowering cholesterol, enhancing athletic performance, and relieving the symptoms of rheumatoid arthritis.[388]

Requirements and Reference Nutrient Intakes

A number of studies have estimated the dietary intake of pantothenic acid in humans to be 4 to 7 mg/day, which seems sufficient for normal health.[299,564] Urinary excretion of pantothenic acid on a typical American diet averages 2.6 mg/day,[564] but may range from 2 to 7 mg/day in adults consuming 5 to 7 mg/day and is strongly dependent on intake; another 1 to 2 mg/day is lost in feces. The primary criterion used to estimate an AI for pantothenic acid is whether its intake is adequate to replace urinary excretion. It has been set at 5 mg/day for adolescents 14 years to 18 years and for adults.[170] Children 1 year to 13 years have AIs extrapolated from adult values, and infants have AIs reflecting intake from human milk, which contains approximately 2 mg/L. An additional 1 mg/day is suggested in pregnancy and an additional 2 mg/day is suggested for lactating mothers.

Intravenous Supply

The recommended intravenous supply for adults is 15 mg/day of dexpanthenol.[9]

Deficiency

The widespread availability of pantothenic acid in food is commensurate with its many roles and makes an uncomplicated dietary deficiency of pantothenate unlikely in humans. Symptoms have been produced in a few volunteers who have received ω-methylpantothenic acid as an antagonist[251] and in people fed semisynthetic diets virtually free of pantothenate.[187] Subjects became irascible and developed postural hypotension and rapid heart rate on exertion, epigastric distress with anorexia and constipation, numbness and tingling of the hands and feet, hyperactive deep tendon

reflexes, and weakness of finger extensor muscles. The eosinopenic response to adrenocorticotropic hormone was impaired. More severe deficiency in animals leads to adrenocortical failure. Historically, pantothenic acid deficiency has been associated with the syndrome of "burning feet," experienced by prisoners in the second World War in Asia, and relieved only by pantothenic acid supplementation, and not by other B-group vitamins.[201]

Toxicity

There are no reports of adverse effects, with the exception of occasional mild diarrhea, with oral pantothenic acid in doses as high as 20 g/day.[457,553] In the absence of evidence of toxicity, a tolerable upper intake level cannot be derived for pantothenic acid.

Laboratory Assessment of Status

There are no convenient or reliable functional tests of pantothenic acid status, thus assessment is made by direct measurement of whole blood or urine pantothenic acid concentrations. Urine measurements are perhaps the easiest to conduct and interpret, and concentrations are closely related to dietary intake.[495] Whole blood measurements are preferred to plasma, which contains only free pantothenic acid and is insensitive to changes in pantothenic acid intake. Concentrations of pantothenic acid in all of the above fluids can be measured by microbiological assay, most commonly using *Lactobacillus plantarum*. Whole blood must first be treated with an enzyme preparation to release pantothenic acid from CoA.[26] Other techniques that have been used to measure pantothenic acid in human samples include radioimmunoassay[629] and gas chromatography.[508] Other techniques that have been developed include gas chromatography–mass spectrometry[28] and a stable isotope dilution assay.[486] CoA and ACP can be measured by enzymatic methods.[109]

Reference Intervals

Urinary excretion of pantothenic acid of less than 1 mg/day is considered abnormally low. Suspicion of inadequate intake is further supported if whole blood levels are less than 100 μg/L. A guidance reference interval for pantothenic acid in whole blood or serum is 344 to 583 μg/L (1.57 to 2.66 μmol/L),[143] and for urinary excretion is 1 to 15 mg/day (5 to 68 μmol/day).[629]

TRACE ELEMENTS

The term "trace element" was originally used to describe the residual amount of inorganic analyte quantitatively determined in a sample. Increased analytical sensitivity now allows the accurate determination of most inorganic micronutrients present at very low concentrations in body fluids and tissue. Those present at (μg/dL) in body fluids and in tissue (mg/kg) are however still widely referred to as "trace elements" and those found at ng/dL or μg/kg as the "ultratrace elements." The corresponding dietary requirements are quoted in mg/day or μg/day, respectively.

The biological effects of deficiency disease define the essential trace elements. For example, an element is considered essential when the signs and symptoms induced by a deficient diet are uniquely reversed by an adequate supply of the particular trace element under investigation.[378,428]

For iron, iodine, cobalt (as cobalamins), selenium, copper, and zinc there are clinical examples of reversible deficiency disease. For these elements there is enough known about their biochemical functions to explain their importance in human nutrition. For others, such as manganese, chromium, molybdenum, and vanadium, their importance remains to be fully accepted in clinical practice. Still other elements such as bromine, fluorine, cadmium, lead, strontium, lithium, and tin have been claimed by at least one investigator to be essential for one or more animal species as demonstrated by dietary deprivation studies.

Classification

This wide range of biologically active elements has led to a suggestion for classification beyond "essentiality" into the additional categories pharmacologically beneficial and nutritionally beneficial or possibly essential.[419]

Pharmacologically Beneficial

Trace elements in this category would include fluoride used for protection against dental caries and lithium salts used in the treatment of manic depression. The dosages required for a beneficial pharmacological effect greatly exceed the amounts of these elements normally found in food.

Nutritionally Beneficial or Possibly Essential

For some trace elements, continued suboptimal dietary intake—in the presence of physiological, nutritional, or other metabolic stress—may eventually have a detrimental effect. Then additional dietary supplementation may have a "health restorative" effect. Such effects are most clearly demonstrated in experimental animals. Examples include the effects of boron in the presence of vitamin D depletion,[260] or the need for increased vanadium when there is either an experimentally induced deficient or excess supply of dietary iodine.[588]

Dose-Effect Relationships

At low intakes of the recognized essential trace elements, deficiency disease may be seen, and then with increasing dietary supply a plateau region of optimal supply is reached. Still higher intakes will result in adverse toxic effects. The concentration window separating beneficial dietary intake from toxic intake varies depending upon the element in question, and on the nature of the chemical species present in the diet. This is similar to the dose-effect relationship described for the organic micronutrients (Figure 30-25). Therefore the RDA is set at amounts that are sufficient to prevent deficiency. A tolerable upper intake value that will

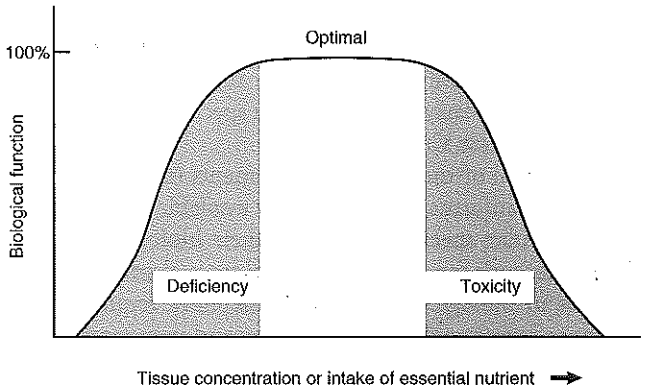

Figure 30-25 Model of the relationship between tissue concentration and intake of an essential nutrient and dependent biological function.

prevent toxicity is also proposed for the inorganic micronutrients of known importance to human health.[174]

Reversal of clinical signs and symptoms by supplementation with a single trace element or with micronutrient mixtures has been used as indirect evidence of a preexisting deficiency. Growth velocities in children, regain of lean body mass, rate of wound healing, resistance to infection, and alterations in cognitive function can be assessed. However, many confounding factors, in particular the presence of disease or of other nutritional deficits, can affect the interpretation of changes in these indices.

Reductions of metalloenzyme activity induced by the deficiency may be partially or wholly restored by effective treatment. Reversal of hematological and immune function laboratory abnormalities can also be used, as can hormonal changes induced by the deficiency.

Chemistry

Trace elements interact with available ligands, mainly the electron donors nitrogen, sulfur, and oxygen to form a wide variety of chemical complexes or species. Some metals such as Fe, Cu, Mo, and Cr are stable in more than one valence state and participate in biologically important oxidation-reduction reactions.[180] The transition metals with an incompletely filled *3d*-orbital (Fe, Cu, and Co) coordinate with a large number of groups to form stable complexes. Zinc lies at the end of the first transition series in the periodic table. Zn^{2+}, with a complete *3d* electron shell, is a particularly stable ion with unique biological functions. Reviews of the biological chemistry of the essential elements are available.[180,428]

Biochemistry/Homeostasis

Most aspects of intermediary metabolism require essential trace elements in the form of metalloenzymes that have a range of catalytic properties. Specific metalloproteins are required for the transport and safe storage of very reactive metal ions, such as Fe^{3+} or Cu^{2+}. Examples are metallothionein (Cu, Zn), transferrin, ferritin and hemosiderin (Fe), and ceruloplasmin (Cu).

Homeostatic controls are required to regulate the supply of essential trace elements to tissue cells in the face of varying dietary intakes. These involve regulation of intestinal absorption, specific transport systems in peripheral blood, uptake and storage mechanisms in tissue, and control of excretion. The principal excretory route for some important trace metals (Zn, Cu) is in feces both by regulation of initial absorption and by resecretion into the intestinal tract in bile and other intestinal fluids. For the halides (iodide and fluoride) excess intake is primarily excreted in urine. For others (Se, B, Mo, and Cr) urinary output is also important. Losses of trace elements by other routes, through hair and/or nails, skin cell desquamation, and in sweat, are generally minor, although studies have been published measuring such losses.[275] Similarly menstrual iron loss or seminal fluid zinc loss could be important in specialized studies.

Combinations of poor dietary supply, intestinal malabsorption because of the antagonistic effects of other trace elements, or blockage of uptake by substances like phytate—together with increased excretory losses as a result of disease, injury, and infection—can result in overt, symptomatic trace element deficiency disease.[47] Liver disease, inflammatory bowel disease, and renal disease will affect trace element absorption and excretion to a variable extent and may cause an acquired deficiency disease.

Catabolic responses to injury, infection, and malignant disease can result in increased essential trace element losses in feces and in urine, and burn injury causes extensive losses in exudates through the damaged skin.[45]

If postsurgical patients, especially those with short bowel syndrome, require prolonged periods of nasogastric tube feeding or intravenous feeding and are treated with nutrient regimens lacking sufficient inorganic micronutrients, they will develop symptomatic deficiency disease. Clinical cases of trace element deficiency have been described for copper, zinc, selenium, and chromium.[525]

Inborn Errors

Although genetic defects in the metabolism of trace elements are rare, they are nonetheless important because of the information they have provided as to homeostatic control mechanisms. This in turn has led to development of effective therapeutic strategies. The most commonly investigated disorders are those affecting iron (hemochromatosis), copper (Wilson's disease and Menkes' syndrome), zinc (acrodermatitis enteropathica), and molybdenum (molybdenum cofactor disease).

Interactions

The physiological interaction between different essential trace elements and also with the other essential major minerals can have significant effects on health. Such interactions are mostly considered as affecting the intestinal bioavailability of nutrients from various diets. The complex interactions that were investigated systematically in animal studies have been important in trying to understand the mechanisms of

absorption by the intestinal mucosal cells, an area that is still poorly defined. Both synergistic and antagonistic effects on bioavailability have been given a theoretical basis by the observation that ions with similar electronic configurations in their outer orbit are likely to interact competitively. For example, there is strong interaction between zinc and copper and also between molybdenum and tungsten.[249]

The ability of zinc ions to block copper absorption, possibly by formation of intestinal metallothionein that strongly binds copper, has led to its use in pharmacological doses in the management of Wilson's disease.[73] Similarly molybdate ion can form insoluble copper-molybdate complexes in the intestine that limit copper absorption. The detrimental effects of organic phosphate (phytic acid) in limiting zinc absorption are aggravated by excess dietary calcium, probably by formation of a highly insoluble Ca-Zn-phytate complex. The subject of these and other interactions has been reviewed.[428]

Synergistic interactions occur in other tissues and can have important biological and clinical consequences. For example, the interaction between selenium and iodine has been investigated.[528] It is known that deiodinases are selenoproteins and that they remove iodine from T_4 to produce the biologically active T_3. Also the selenoprotein glutathione peroxidase is active in the thyroid in the destruction of excess hydrogen peroxide and is therefore important in thyroid hormone production. In certain areas of the world, combined selenium and iodine deficiency can occur and affect treatment; provision of selenium may be necessary to correct hypothyroidism, but also may precipitate its onset.[19,528]

Selenium deficiency in experimental animal studies is exacerbated by vitamin E depletion. The antioxidant properties of tocopherol and glutathione peroxidase are similar and can to some extent overlap, although this is highly species dependent.[550]

Zinc and vitamin A are also interrelated, and it appears that zinc depletion limits the bioavailability of vitamin A. Controlled studies found that combined zinc and vitamin A supplementation is more clinically effective than vitamin A alone or zinc alone in controlling diarrhea and minimizing respiratory infections.[455]

Experimentally, it is usual to conduct animal and human studies using depletion of one essential element at a time. It is likely that in vivo the circumstances causing depletion of one essential element will be accompanied by varying degrees of depletion of other micronutrients, and that the possibility of interactions and synergistic effects should be considered when designing therapies.

Laboratory Assessment of Trace Element Status

As understanding of underlying biochemical intracellular mechanisms increases for a particular trace element, the determination of the active species becomes of increased importance.[390,567] For iodine, assay of the thyroid hormones and of their control and feedback systems has largely replaced direct determination of the element. Cobalamin (vitamin B_{12}) is measured in body fluids by immunoassay rather than by a nonspecific cobalt determination. This process is gradually extending to other trace elements, because metalloenzymes and protein species are proposed as indices of Fe, Zn, Cu, and Se status.

For several of the "ultratrace" elements (Cr, Mo, and V), insufficient information is currently available as to the critical molecular species underlying their biological actions. Direct methods for determining total trace element concentrations in biological samples are therefore required. This can pose severe analytical difficulties, and may require specialist laboratory facilities, with appropriate techniques employed to reduce sample contamination.[390]

Dietary intakes of trace elements can be assessed for individual patients or population groups by direct dietary analysis and by taking dietary histories. The estimated intakes can then be compared with the current dietary reference values.

Direct measurement of total dietary intake over several days together with measurement of all outputs in urine, feces, or by other routes can be used to estimate positive or negative balances. Because of the intrinsic difficulty of ensuring complete collection of all materials with minimal contamination, metabolic balance studies can have systematic errors.[380]

The net intake can be also be estimated by using exogenous and endogenous labeling of representative diet with radio or stable isotopes of the trace element under investigation. These research methods can give valuable insights as to the bioavailability of nutrients and the efficiency of uptake by the intestinal tract from particular diets.[436]

Analytical Considerations

Analytical factors that have to be considered in the measurement of trace elements include (1) specimen requirements, (2) preanalytical factors, (3) collection equipment, and (4) analytical methodology.

Specimen Requirements

Direct determination of trace elements is made in many types of specimens including whole blood, blood plasma or serum, leukocytes, urine, saliva, cerebrospinal fluid (CSF), breast milk, and sweat. Tissue samples may be obtained by needle biopsy (liver, bone,) or following an autopsy. Hair and nail samples offer a noninvasive means of sampling tissue and are used to assess toxic metal exposure. Measurements of hair and nails for essential elements may be of value on a group basis during studies of severely depleted populations but are of limited value in the investigation of individual hospital patients. Problems of external contamination from environmental pollution, cosmetics, shampoos, and other sources are difficult to control.[220]

The most commonly submitted samples for direct trace element analysis are of whole blood, blood plasma, or serum. Plasma protein levels of the relevant carrier proteins transferrin (Fe), albumin (Zn), ceruloplasmin (Cu), and selenoprotein P (Se) can give useful additional information.

The concentration of essential trace elements in nucleated cells can be determined in various types of leukocytes and in platelets; this is a direct measure of intracellular trace element levels. However, separation of different types of white cells and platelets in whole blood is subject to serious problems of contamination before trace element analysis.[392]

Problems from prolonged storage of samples can arise and short-term storage at 4 °C to 10 °C with a rapid turnaround analytical time is good practice. Repeated freezing and thawing of blood plasma and other types of material can lead to precipitation of proteins and nonhomogeneous samples.

Preanalytical Factors

There are numerous variables that can affect trace element determinations before the analysis of the sample is undertaken and these require careful control. Guidelines giving details of sample collection procedures, and procedures for limitation of contamination in a range of sample types, are available for essential and toxic trace elements.[338,390] Age, sex, ethnic origin, time of sampling in relation to food intake, time of day and year, history of medication, tobacco usage, and other factors should be recorded when establishing reference intervals from healthy control populations.

For hospital patients with infections, and after accidental injury or postsurgery, the systemic inflammatory response will affect the concentration of essential elements in circulating blood independently of nutritional status. For example, the APR causes increased permeability of capillaries and transfer of certain plasma carrier proteins and their trace metals into interstitial space. Hepatic synthesis of some plasma proteins, the so-called acute phase proteins, is also induced, so that these proteins increase in concentration in plasma, together with any metals that they carry (e.g., ceruloplasmin and copper). Moreover, there are marked changes in the kinetics of elements, with altered rates of transfer to and from the tissue. Knowledge of the effect of disease on metal kinetics and distribution is therefore essential.[523]

Collection Equipment

The choice of container for samples is important, since contamination from rubber, cork, and colored plastics can be a problem. For blood plasma, collection plastic tubes with lithium heparin as an anticoagulant are suitable for most analyses. For blood serum, plain glass containers can be used. For the ultratrace metals (Mn, Cr), special arrangements have to be made to collect blood via plastic cannulae or silanized steel needles, and then the sample is placed into acid-washed containers. "Trace metal" vacutainers are available commercially. It is good practice to run dilute acid blanks through all the containers and collection systems to ensure that all batches remain as free from contamination as possible.

For random urine samples and for tissue biopsy samples, a plain plastic container is preferable with no added preservative. For 24-hour urine collections, polyethylene bottles should be used with glacial acetic acid as the preservative. It is important that the urine collections should not be made into disposable fiber or stainless steel containers.

For further details and advice, specialist laboratories should be consulted (e.g., in the United States, the United States Department of Agriculture (USDA), Beltsville Agricultural Research Center (BARC), Washington D.C.,[424] or the U.S. Department of Agriculture, Agriculture Research Service Human Nutrition Research Center, Grand Forks, N.D.[393] UK and European readers may wish to consult the Supra Area Assay Service[494] or the Scottish Trace Element and Vitamin Laboratory).[577] These sites have links to other specialist laboratories.

Analytical Methodology

An analytical method used for the determination of trace and ultratrace elements in biological specimens must be (1) sensitive, (2) specific, (3) precise, (4) accurate, and (5) relatively fast. The detection limits of such methods are very important because concentrations of trace or ultratrace elements in some samples are in the nanogram per gram to microgram per gram range. In practice, the concentration of a trace or ultratrace element should be about at least 10 times the detection limit of the method, thus ensuring sufficient accuracy and precision.

Analytical techniques used for clinical trace metal analysis include photometry, atomic absorption spectrophotometry (AAS), inductively coupled plasma optical emission (ICP-OES), and inductively coupled plasma mass spectrometry (ICP-MS). Other techniques, such as neutron activation analysis (NAA) and x-ray fluorescence (XRF), and electrochemical methods, such as anodic stripping voltammetry (ASV), are used less commonly. For example. NAA requires a nuclear irradiation facility and is not readily available and ASV requires completely mineralized solutions for analysis, which is a time-consuming process.

Photometry

The principals of photometric measurements are discussed in Chapter 3. When applied to the analysis of trace elements, photometric methods are based on the use of a color-forming reagent; however, they are not specific for a particular metal. Interferences also occur in hemolyzed, lipemic, and icteric samples. In practice, the technique lacks sufficient sensitivity for all but the more abundant trace elements, such as iron, zinc, and copper. Many photometric methods for zinc and copper have been described[1,71,255,357] and kits for them are available commercially.

Atomic Absorption Spectrophotometry

AAS is a widely used method for the determination of Zn and Cu in serum and has largely replaced less specific photometric methods. (The principles of AAS are detailed in Chapter 3 and elsewhere,[55,127] and Delves has written a useful review on the application of AAS to clinical pathology.)[128]

Unfortunately the technique lacks the sensitivity to measure Cu in urine and the more sensitive but technically more demanding electrothermal atomization atomic absorp-

tion spectrometry (ETA-AAS) is required. In this technique, sample volumes as small as 10 µl are sequentially volatilized and atomized in a graphite tube. This technique is useful in situations in which the sample volume is limiting (e.g., premature babies) or for elements in which increased analytical sensitivity is required, such as selenium or manganese. Significant analytical errors can result from nonspecific optical absorption in the graphite tube and are caused by matrix components being volatilized along with the analyte atoms. Optical background correction systems using a deuterium lamp or employing the Zeeman effect are now standard components in ETA-AAS instrumentation (see Chapter 3). Flame and electrothermal AS are therefore widely used, but these are single element techniques and as such the methods for different elements have to be run sequentially, which can be wasteful in terms of time and sample.

Inductively Coupled Plasma-Optical Emission Spectrometry (ICP-OES)

ICP-OES is replacing AAS in some laboratories. Major changes to ICP-OES instrumentation that have led to this trend in replacement include (1) use of conventionally or radially viewed plasmas, which can now be viewed axially thereby greatly improving sensitivity; (2) replacement of monochromators with echelle spectrometers; (3) replacement of photomultiplier detectors with charge-coupled detectors (CCD), which have the ability to capture the whole echellogram and thereby deliver truly simultaneous analysis over the entire spectrum; and (4) use of vacuum or argon purged optics, allowing measurement down to and including the primary aluminum line at 167 nm.

With up-to-date ICP-OES, the elements Ca, Mg, Zn, Cu, Fe, and Al can be determined in a single analysis.[103,454] Apart from its multielement capabilities and increased sensitivity, ICP-OES also offers a wide dynamic range (e.g., three orders of magnitude for most elements) that allows simultaneous analyses to be obtained on a single diluted aliquot of sample. The high temperature of the plasma, 7500 °C, renders the technique largely free of chemical interferences, but matrix effects, background, and spectral interferences are greater than those in AAS. This is especially true of the axially viewed plasma in which emission from metal oxides may be observed. However, it is expected that sophisticated algorithms built into the software of modern instruments will overcome most problems. Axially and radially viewed ICP has been compared with respect to signal/background ratio, matrix effects, and sodium and calcium interferences.[70,139]

Inductively Coupled Plasma-Mass Spectrometry (ICP-MS)

This technique is more sensitive than either ETA-AAS or ICP-OES and is now the method of choice for ultratrace elements. The spectra are simpler than those of ICP-OES, but isobaric and polyatomic interferences do occur. Polyatomic interferences are more likely at masses <80. As ICP-MS can also be used to measure stable isotopes, it is used for conducting stable isotope tracer experiments and isotope dilution analysis. The principles of mass spectrometry are discussed in Chapter 7 and several textbooks are available on ICP-MS.[248,565] Clinical applications of ICP-MS have been described and reviewed.[452]

Quality Assurance Considerations

Because methods for trace element analyses are not standardized and are disposed to matrix effects and contamination problems, quality assurance measures must be incorporated into trace element analysis schemes. An effective quality assurance scheme for trace or ultratrace element analyses requires incorporation of the following into each batch of analysis: (1) reagent blanks, (2) replicate analyses to assess precision, (3) calibrators of the trace elements of interest in the expected concentration range of the specimens analyzed, and (4) a control or reference solution with known or certified concentrations of the trace elements to be determined to assess accuracy and batch-to-batch precision. The reference material should be of the same matrix type and contain approximately the same amounts of analyte as the specimens. Many different control or reference materials that contain certified amounts of trace elements are available. For quality control of trace element determinations in tissue specimens, reference materials of different biological matrices that have certified values for most macro and trace elements are available from the National Institute of Standards and Technology, Office of Standard Reference Materials in Washington, D.C. and from the Institute for Reference Materials and Measurements (IRMM) in Geel, Belgium (see Chapter 1).

A specimen pool that has been characterized by more than one laboratory can be conveniently and reliably used for quality control. Aliquots of such a pool should be stored frozen in tightly capped polypropylene tubes, with a minimum of headspace. No changes in zinc or copper concentrations were seen in serum samples frozen for up to 50 days.[163] Frozen pool samples can also be used to assess day-to-day precision of methods. Thawed specimens should be well mixed before sampling because analytical errors are caused by metal concentration gradients in unmixed thawed specimens. Recovery studies of elements from samples containing known quantities of added analyte are useful at intervals, for assessing accuracy and linearity, but such studies do not have to be performed daily. It is also recommended that trace elements participate in one or more EQAS. Organizations providing such schemes are listed in Box 30-1 and compilations of reference intervals have been published.[178,601]

Individual Trace Elements

Trace elements include chromium, cobalt, copper, fluoride, iron, manganese, molybdenum, selenium, and zinc.

Chromium

Chromium (Cr), which occurs naturally in various crustal materials, is a transitional element with many industrial

uses and is discharged into the environment as industrial waste.

Chemistry

Chromium (atomic number 24, atomic weight 51.99) is a transition metal that occurs in biology with valence 3^+ or 6^+, each having markedly different properties. Trivalent Cr^{3+} is a d^3 cation, which usually forms octahedral complexes with slow ligand exchange. The element has no redox or acid-base properties.[180] It is considered an essential trace element that enhances the action of insulin.[382] Hexavalent Cr^{6+} is a strong oxidant and can cause tissue damage,[587] although the toxic Cr^{6+} ion is normally rapidly reduced to Cr^{3+} during contact with foodstuffs and gastric contents.

The molecular composition of a biologically active form of Cr^{3+} found in brewer's yeast, known as glucose tolerance factor (GTF), is not established. The structure of the Cr^{3+} bioactive molecule is thought to be the octahedral chromium complex, with two molecules of nicotinic acid having four coordination sites linked to glutamic acid, glycine, and cysteine, but attempts to isolate and purify the substance have not been successful. It is not clear whether GTF in brewer's yeast is better used than inorganic chromium in relation to insulin activation.[430]

Dietary Sources

Estimates of the amount of chromium in foodstuffs vary, partly because of analytical difficulties, but also because of contamination during contact with stainless steel during food processing, storage, and cooking. Processed meats, whole grain products, green beans, broccoli, and some spices are relatively good sources, but fruit and dairy products are not. Foodstuffs with high amounts of sucrose or fructose are intrinsically low in chromium and furthermore these sugars may promote urine loss. The estimated dietary intake for adults in the United States varies from 20 to 30 μg/day. Sup-

plements containing chromium are taken by about 8% of adults in the United States and the NHANES III survey estimated that this added 23 μg Cr per day.[174]

Absorption, Transport, Metabolism, and Excretion

Intestinal absorption of Cr^{3+} is low, ranging from 0.4% to 2.5%, so fecal output is mainly unabsorbed dietary chromium. Absorption is increased marginally by ascorbic acid, amino acids, oxalate, and other dietary factors. After absorption, chromium binds to plasma transferrin with an affinity similar to that of iron.[231] It then concentrates in human liver, spleen, other soft tissue, and bone.[333] Urine chromium output is around 0.2 to 0.3 μg/day, the amount excreted being to some extent dependent upon intake. Paradoxically, urine output appears to be relatively increased at low dietary levels. Thus 2% is lost in urine at an intake of 10 μg/day, but only 0.5% at an intake of 40 μg/day.[14] Both running and resistive exercise increases urine chromium excretion.[15,481]

Functions

Severely chromium-deficient rats have impaired growth, reduced lifespan, corneal lesions, and alterations in carbohydrate, lipid, and protein metabolism. Supplementation with inorganic chromium restored glucose tolerance in these animals. Repetition of laboratory studies on experimental animals by other groups gave inconsistent results. Claims of benefits from chromium supplementation in diabetic patients, the elderly, and malnourished children were published but also not confirmed by others. It was later realized that analytical methods for chromium determination used in some of the earlier studies were orders of magnitude too high because of contamination of samples before analysis. Also, ineffective background optical correction was used in the graphite furnace AAS systems then available.[217,596] However, many of the important biological observations made in those early investigations have since been confirmed using more accurate analytical techniques.[381]

The biochemical mechanism that allows chromium to potentiate the actions of insulin receptors on cell membranes has been intensively investigated.[603] It is now suggested that a low molecular weight intracellular octapeptide (LMWCr), also known as chromodulin, binds Cr^{3+} and enhances the response of insulin receptors. Chromodulin binds four Cr^{3+} ions and then locates on cell membranes near to the site of insulin receptors. The structure of chromodulin has been examined by a variety of advanced spectroscopic techniques and the complex shown to possess a unique type of multinuclear assembly, with the chromium centers having an octahedral coordination with oxygen-based ligands.[278]

Chromodulin, first described in the 1980s, has been isolated from liver, kidney, and other tissues in several species of experimental animals. Its proposed mode of action is (1) the inactive insulin receptors on cell membranes are converted to an active form by binding circulating insulin; (2) this binding stimulates the movement into cells of chromium bound to plasma transferrin; (3) chromium then binds to apoLMWCr, converting it to an active form that then binds to the insulin receptors and potentiates kinase activity; (4) as plasma glucose and insulin fall to normoglycemic levels, the LMWCr factor is released from the cell to terminate its effects. It is thought that the released chromodulin is the naturally occurring form of chromium in urine.[111]

Requirements and Reference Nutrient Intakes

Because there has not been sufficient evidence to set an estimated average requirement (EAR), an AI based on estimated intakes has been set at 35 μg Cr per day for men and 25 μg Cr per day for women. No tolerable upper limit was set for dietary Cr^{3+} intake.[174]

Intravenous Supply

It is now advised that patients on short-term TPN (<1 to 3 months) receive 10 to 20 μg Cr per day. Those on long-term TPN who are clinically and biochemically stable may be receiving enough chromium via contamination of their nutrients.[11]

Commercial multielement intravenous additives will usually contain about 10 to 30 μg Cr. When high concentrations of glucose (20% to 50%) are given intravenously as the main energy source, increased losses of chromium in urine may occur. Urinary losses could be monitored (although this is rarely done) and input increased especially if signs of unexplained glucose intolerance are seen. However, there also have been reports that excessive amounts of chromium may have been given to children and adults during TPN, with possible detrimental effects on renal function.[221,329]

Deficiency

Clinical signs of human chromium deficiency were first clearly described in patients receiving parenteral nutrition for a prolonged period using a nutritional regimen that did not supply sufficient chromium.[11] Only a few case histories been have published.[81,184,284] All had similar presentations, with previously stable patients developing insulin-resistant glucose intolerance, weight loss, and in some cases neurological deficits. Addition of substantial amounts of Cr^{3+} to the intravenous regimen (150 to 200 μg/day) reversed glucose intolerance and reduced insulin requirements with eventual improvement in the neurological disorders.

It was later noted that a patient on TPN who developed glucose intolerance and neuropathy also had been receiving metronidazole. Baseline serum chromium concentrations were seemingly increased. Yet treatment with 250 μg chromium chloride intravenously for 2 weeks resulted in rapid clinical remission, and normal nerve conduction was restored within 3 weeks.[600]

These cases, although rare, influenced the U.S. Food and Nutrition Board to designate chromium as an essential trace element.[174] It is not clear why there have been so few cases of clinical chromium deficiency in comparison with zinc,

copper, and selenium, but this might relate to chromium contamination of infusion fluids, especially in the amino acid mixture.[520]

Clinical Significance

Chromium is thought to play a role in impaired glucose tolerance, diabetes, and cardiovascular disease.

Impaired Glucose Tolerance and Diabetes. More than 15% of adults aged 40 to 74 are thought to have impaired glucose tolerance and it has been suggested that poor chromium nutritional status may be a factor.[174] However, the variability of dietary chromium intake and the lack of an easily usable laboratory or clinical marker to identify those patients with poor chromium status create difficulties. A metaanalysis investigated 15 randomized controlled trials that reported adequate data on the effect of chromium on glucose, insulin, and glycated Hb A_{1c}. Of the 618 participants, 193 had type 2 diabetes and 425 of the subjects were either in good health or had only impaired glucose tolerance.[8] The authors concluded that there was no effect from chromium on glucose or insulin in nondiabetic participants and that the data for persons with diabetes are inconclusive. Consequently, large scale trials are required.

A controlled trial of higher doses (250 µg and 1000 µg of chromium) as chromium picolinate was conducted in China on 180 type 2 diabetic subjects. This trial did find improvements in glucose handling and reduction in glycosylated hemoglobin.[13] Benefit was also found in previous studies on populations of malnourished children in Jordan, Nigeria, and Turkey. It is possible that other interacting dietary depletions may aggravate chromium deficiency in these populations.[382]

It has now been suggested that short-term dosage of <1000 µg Cr per day may be a useful additional treatment for type 2 diabetes. Monitoring of kidney function and clinical assessment of any dermatological changes are advised.[485] Anderson maintains that chromium supplementation has been shown to improve glucose handling in all the main types of diabetes.[12] The dosages used suggest a pharmacological role for chromium and potential toxicity has to be considered and therapeutic benefit.[283] Chromium therapy in the control and prevention of diabetes is therefore of considerable interest and the subject of much controversy.[293]

Glucose Intolerance in the Elderly. Glucose intolerance is age related and chromium supplementation trials in the elderly have been conducted with variable results.[430] The inability to determine which of the elderly trial subjects was initially chromium depleted makes it difficult to interpret the findings. If the observations can be confirmed and there is an age-related decrease in the chromium concentration in hair, sweat, and blood serum, then there is a necessity for further studies in the elderly.[125]

Cardiovascular Disease. Chromium depletion has long been thought to be associated with an increased cardiovascular risk.[379,504] A double-blind 12-week study of 23 healthy adult men showed that 200 µg chromium (as chromium chloride) increased HDL cholesterol and decreased insulin levels.[465] Other reports of favorable lipid responses to chromium supplementation have also been published.[2,244] Abnormal lipid profiles are found in patients with type 2 diabetes and may be associated with an increased risk of cardiovascular disease. However, additional larger-scale studies are necessary to confirm the effects of chromium on risk factors for cardiovascular disease.[430]

Toxicity

Hexavalent chromium (6^+) is a recognized carcinogen, and industrial exposure to fumes and dusts containing this metal is associated with increased incidence of lung cancer, dermatitis, and skin ulcers. Environmental health risks arise from soil contamination by Cr^{6+} waste disposal sites left by the leather tanning and dyestuff industries.[587] Cr^{6+} is more efficiently absorbed than Cr^{3+} and its toxicity and carcinogenic effects involve reduction to $Cr^{5+}$and Cr^{3+} by cysteine, with the formation of intracellular DNA adducts.[638] Cr^{3+}species are relatively nontoxic partly because of their poor intestinal absorption and rapid excretion in urine.

However, chromium picolinate is a widely used dietary supplement and this compound has been reported to cause renal and hepatic damage when used at high doses.[100] Patients with preexisting renal or liver disease may be at particular risk from adverse effects. Vincent[604] has found that chromium picolinate has a different intracellular pathway from other forms of Cr^{3+}. There may be benefits from chromium picolinate in relation to diabetes control,[13] but the claims that this supplement can promote body fat loss and muscle mass gain have not been substantiated.[604]

Laboratory Assessment of Status

A beneficial response of glucose-intolerant patients to chromium supplementation is presently the only means of confirming chromium deficiency. No practicable method of assessing intracellular chromium depletion is yet available and there is no consistently reliable animal model for chromium deficiency. Furthermore, it has been known from early animal experiments that circulating chromium is not in equilibrium with physiologically important reserves.[381] It has been shown in late pregnancy that serum chromium concentration does not correlate with glucose intolerance, insulin resistance, or serum lipids.[216]

A possibly useful test has been proposed that uses radioactive $^{51}Cr^{6+}$ to label red cells. The ion is then reduced to Cr^{3+} and the amount bound to cell membranes is dependent upon the initial amount of Cr^{3+} present, which in turn is a reflection of the adequacy of chromium nutritional status. The test was applied to 25 type 2 diabetes patients and 35 controls. No difference was found, and it was concluded that chromium nutrition has only a minor role in this condition.[615]

Direct determination of chromium in diet, in oral and intravenous nutritional support regimens, and in blood

plasma or serum can only be carried out if great care is taken to prevent contamination before and during analysis.[430] Sample collection procedures have to avoid any contact with stainless steel, so all-plastic phlebotomy systems or siliconized steel needles should be used, and samples should be stored in acid washed containers. Acid digestion of diet samples in sealed pressure vessels using microwave heating may be necessary to reduce background effects and also to prevent losses of volatile chromium compounds. Specialist trace element laboratories employing ICP-MS and stable chromium isotopes[602] now offer improved analytical sensitivity and allow tracer methods for metabolic studies.[436]

The detection of increased amounts of chromium in urine is a confirmation of recent occupational or environmental exposure to excess chromium. It also may be useful to monitor urine chromium in trials that use pharmacological dosages of chromium, both to confirm compliance and to detect potential toxicity. This is possible using available graphite furnace AAS instrumentation.[217,225]

Reference Values

Very low values are now considered as normal for serum (0.1 to 0.2 µg/L, 2 to 3 nmol/L) and for urine <0.2 µg Cr per L (<3 nmol/L). Thus the detection of deficiency by direct analysis is difficult.[430,596]

Cobalt

Cobalt (Co) is essential for humans only as an integral part of vitamin B_{12} (cobalamin). No other function for cobalt in the human body is known. Details of vitamin B_{12} biochemistry and function are discussed above. Microflora of the human intestine cannot use cobalt to synthesize physiologically active cobalamin. The human vitamin B_{12} requirement must be supplied by the diet. Free (nonvitamin B_{12}) cobalt does not interact with the body vitamin B_{12} pool.

Copper

Copper (Cu) is an important trace element and is associated with a number of metalloproteins. It is present in biological systems in both the 1^+ and 2^+ valence states.

Chemistry

Copper (atomic number 29, atomic weight 63.54) has Cu^{1+} and Cu^{2+} oxidation states in biological systems; the facile exchange between these ions gives the element important redox properties. Because of their high electron affinities, these ions are the most strongly bound to organic molecules of all the essential trace metals. Copper in biological material is complexed with proteins, peptides, and other organic ligands. An elaborate series of binding and transport proteins inside cells protects the genome from copper-generated free radical attack.[336] This keeps the concentration of free copper in the cytoplasm very low (around 10^{-15} mol/L.) Copper bioinorganic chemistry evolved concurrently with that of molecular oxygen. Numerous blue-colored copper-containing proteins, most of which are oxidases, are located outside the cytoplasm on the surface of cell membranes or in vesicles. However, the copper metalloenzyme superoxide dismutase (SOD) protects against random free radical damage both in the cytoplasm and in blood plasma. Paradoxically, it was the ability of copper ions to generate free radicals that led to the evolutionary development of the extracellular matrix by polymerization and cross-linking of low molecular weight substrates. This allowed the formation of collagen, chitin, and other structural proteins essential for the development of multicellular life forms.[180]

Dietary Sources

The copper content of food is variable and can be affected by applications to crops of copper-containing fertilizers and fungicidal sprays. Also the use of copper-containing cooking vessels contributes to total intake. The metal is most plentiful in organ meats, such as liver and kidney, with relatively high amounts also being found in shellfish, nuts, whole grain cereals, bran, and all cocoa-containing products. Lower amounts of copper are found in white meats and in dairy products, especially cow's milk. The median intake of copper in the United States is around 1.0 to 1.6 mg/day.[174]

Absorption, Transport, Metabolism, and Excretion

Copper absorption mainly occurs in the small intestine, although gastric uptake has been shown to occur to a smaller extent. Some copper may also be incorporated by inhalation and skin absorption. The extent of intestinal copper absorption varies with dietary copper content and is around 50% at low copper intakes (<1 mg Cu per day) but only 20% at higher intakes (>5 mg Cu per day).[580] Copper intestinal uptake is pH dependent and relatively efficient. Absorption is reduced by other dietary components, such as zinc (via metallothionein), molybdate, and iron, and increased by amino acids and by dietary sodium.[230]

Absorbed copper is transported to the liver in portal blood bound to albumin, where it is incorporated by the hepatocytes into cuproenzymes and other proteins and then exported in peripheral blood to tissue and organs. Although two thirds of the 80 to 100 mg total body copper content is located in the skeleton and muscle, the liver is the key organ in copper homeostasis.[580] More than 90% of the copper exported from the liver into peripheral blood is in the form of the glycoprotein ceruloplasmin, which has a blue color when separated from other plasma proteins. Its structure can be studied by electron paramagnetic resonance spectroscopy and other spectroscopic techniques.[355] It is a positive acute phase reactant and increases during infection and after tissue injury. Ceruloplasmin also increases in pregnancy and during use of oral contraceptives, leading to a rise in serum copper concentration. A smaller amount of copper in plasma (<10%) is bound to albumin by specific peptide sequences and this copper is in equilibrium with plasma amino acids. This fraction may be important for cellular uptake.

An overview of copper metabolism is illustrated in Figure 30-26.[230]

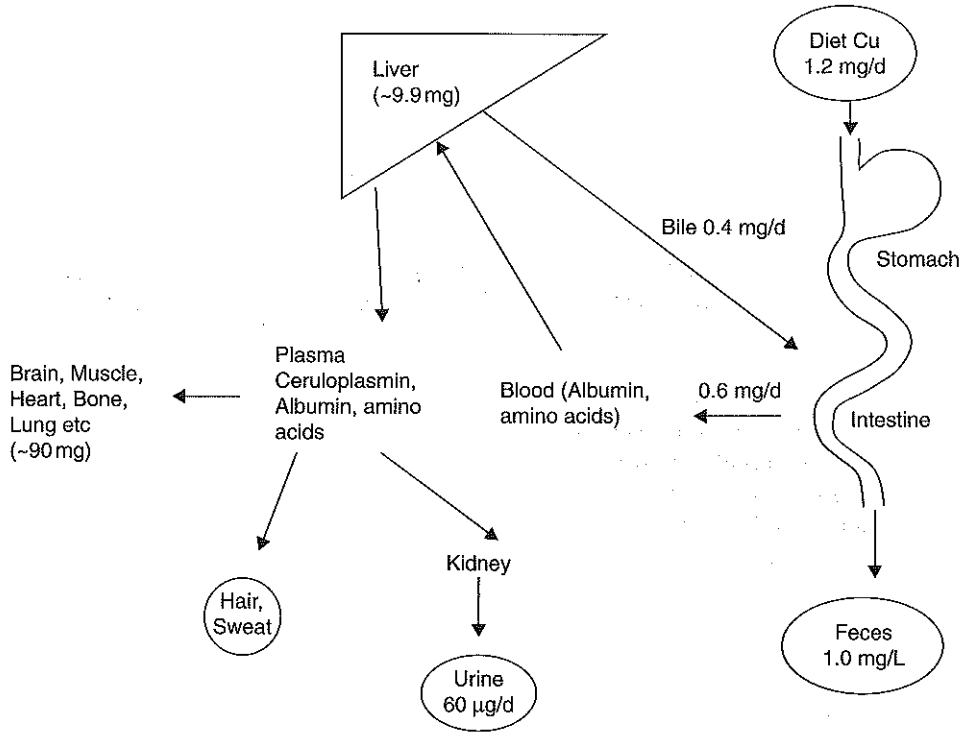

Figure 30-26 Metabolism of copper. *(Modified from Harris ED. Copper. In: O'Dell BL, Sunde RA, eds. Handbook of nutritionally essential mineral elements. New York: Marcel Dekker, 1997:231-73.)*

Between 0.5 and 2.0 mg of copper per day is excreted via bile into feces. Patients with cholestatic jaundice or other forms of liver dysfunction are therefore at risk of copper accumulation caused by failure of excretion. Copper losses in urine and sweat are <3% of dietary intake. Urine copper output is normally less than 60 µg/day.

Functions

Copper is a catalytic component of numerous enzymes and is also a structural component of other important proteins in humans, animals, plants, and microorganisms.[180,230,337] Some of those considered of potential importance in human biochemistry are briefly described below.

Energy Production. Cytochrome c oxidase is a multisubunit complex containing copper and iron. Located on the external face of mitochondrial membranes, the enzyme catalyzes a four-electron reduction of molecular oxygen, establishing a high-energy proton gradient across the inner mitochondrial membrane, which is necessary for ATP production. Cytochrome c and cytochrome c oxidase are essential for oxidative phosphorylation that is the basis of intracellular energy production.

Connective Tissue Formation. Protein-lysine 6-oxidase (lysyl oxidase) is a cuproenzyme that is essential for stabilization of extracellular matrixes, specifically the enzymatic cross-linking of collagen and elastin. Complex mechanisms involve the deamination of lysine and hydrolysine residues at specific extracellular sites. The enzyme is highly associated with connective tissue and located in the aorta, dermal connective tissue, fibroblasts, and the cytoskeleton of many other cells.

Iron Metabolism. Copper-containing enzymes—namely ferroxidase I (ceruloplasmin) and ferroxidase II, and the recently described hephaestin in the enterocyte—oxidize ferrous iron to ferric iron. This allows incorporation of Fe^{3+} into transferrin and eventually into hemoglobin. Ferroxidase II is a yellow protein, the importance of which in iron metabolism is not as well characterized as that of ceruloplasmin.

Central Nervous System. Dopamine monooxygenase (DMO) is an enzyme that requires copper as a cofactor and uses ascorbate as an electron donor. This enzyme catalyzes the conversion of dopamine to norepinephrine, the important neurotransmitter. There are soluble and membrane-bound forms of the enzyme, the latter being found in the chromaffin granules of the adrenal cortex. Monoamine oxidase, one of the numerous amine oxidases, is a copper-containing enzyme that catalyzes the degradation of serotonin in the brain and is also involved in the metabolism of the catecholamines.

The formation of the phospholipids necessary for myelin sheath formation is affected by cytochrome c oxidase depletion. It is now known that the prion protein (PrP) binds Cu II and may be involved in copper regulation within the brain.[86]

Melanin Synthesis. Tyrosinase is a copper-containing enzyme that is present in melanocytes and catalyzes the synthesis of melanin. Starting with L-dopa as a substrate, tyrosi-

nase catalyzes multiple oxidative steps to produce the melanin biopigments pheomelanin and eumelanin.

Antioxidant Functions. Both intracellular and extracellular SODs are copper- and zinc-containing enzymes, able to convert superoxide radicals to hydrogen peroxide, which can be subsequently removed by catalase and other antioxidant defenses. The plasma protein ceruloplasmin also binds copper ions and thus prevents oxidative damage from free copper ions, which can generate hydroxyl radicals.

Regulation of Gene Expression and Intracellular Copper Handling. Copper-dependent proteins act as transcription factors for specific genes, such as those regulating SOD and catalase. Metallothionein synthesis is controlled by copper-responsive transcription factors, and this protein is important in regulating the intracellular distribution of copper.[581] Additional specialized proteins act as "copper chaperones" to deliver copper to intracellular sites and prevent oxidative damage by free copper ions.[162]

Inborn Errors of Copper Metabolism. Menkes' syndrome is caused by a defective gene that regulates the metabolism of copper in the body. Wilson's disease is inherited as an autosomal recessive trait having a defect in the metabolism of copper, with accumulation of copper in the liver, brain, kidney, cornea, and other tissues. Investigation of these rare genetic defects has been of great value in uncovering details of the control of copper transport. Copper-transporting P-type ATPases, known as ATP7A and ATP7B, are essential factors in maintaining copper balance.[120,617] Impaired intestinal transport of copper caused by a mutation in the ATP7A gene leads to the severe copper deficiency disease seen in Menkes' syndrome. Defects in the ATP7B gene affect both incorporation of copper into ceruloplasmin and copper excretion via bile. This results in a toxic accumulation of copper and is the basis of Wilson's disease.

Another genetic defect results in failure of hepatic synthesis of ceruloplasmin (aceruloplasminemia), which is a neurodegenerative disease. Retinal damage, secondary iron overload, and insulin-dependent diabetes present in the fourth to fifth decade of life.[232,242]

Requirements and Reference Nutrient Intakes

The recommended dietary intake for adults is 0.9 mg/day. This is close to the lower limit of 1.0 mg/day found in dietary surveys and has led to suggestions that marginal copper depletion could be found in the U.S. population.[309] The tolerable upper limit is 10 mg/day.[174]

Intravenous Supply

The usual adult supply of copper intravenously varies from 0.3 to 1.3 mg/day (5 to 20 μmol/day), the higher amounts being required in those patients with preexisting depletion or biliary losses and lower amounts in those with cholestasis.

Deficiency

Malnourished Infants. When malnourished infants with a history of chronic diarrhea were rehabilitated using a formula based upon cow's milk, they developed an iron-resistant anemia, neutropenia, and other hematological disorders and bone lesions.[118] Copper supplementation of milk feeds reversed these abnormalities and addition of 2.5 mg Cu per day is now advised.[118]

Premature Infants. Most of the accumulation of copper in the fetal liver occurs in the last 3 months of pregnancy, and premature infants fed formula lacking sufficient copper are at risk of deficiency disease since they lack adequate liver copper stores. Hematological abnormalities and easily fractured brittle bones have been described.[345] The radiographic changes in infants with copper deficiency include osteopenia and metaphyseal spurs.[214] As noted above, formulas based on cow's milk require copper supplementation. Monitoring of plasma copper is advisable and results should be related to postnatal age; at 4 weeks mean values are 42 μg/dL (6.6 μmol/L), rising to 55 μg/dL (8.7 μmol/L) by 14 weeks.[87]

Nutritional Support. Adults and children fed intravenously without addition of sufficient copper to the nutrient regimen develop symptomatic copper deficiency. The hematological changes of hypochromic anemia and neutropenia are reversed by copper supplementation.[189,190] Similar effects have been reported during prolonged enteral feeding via jejunostomy.[89] Children may also develop the typical bone changes mentioned above.

Menkes' Syndrome. The history and aspects of the diagnosis and therapy of this condition have been reviewed.[291] It is a rare condition (1/100,000 live births), the mutation is X-linked, and typically occurs in male infants at 2 to 3 months. They present with loss of previously normal development, hypotonia, seizures, and failure to thrive. Physical changes in the hair (pili torti), in facial appearance, and neurological abnormalities suggest the diagnosis. Low levels of copper in plasma, liver, and brain occur because of impaired intestinal copper absorption. Local first line tests would be finding plasma copper of <10 μmol/L, ceruloplasmin <220 mg/L, and demonstration of pili torti by microscopic examination of hair. Further tests can demonstrate failure of isotopic copper egress from cultured fibroblasts and show plasma catecholamine abnormalities. Placental copper measurement and direct mutation analysis are additional investigative procedures. Deficiency of the copper enzyme DMO in CSF is thought to be an important finding that allows early diagnosis. The effectiveness of therapy with parenteral copper histidine is debatable, although success has been claimed in less severely affected cases, especially if treatment is started early.[108]

Malabsorption Syndromes. Patients at risk include those with celiac disease, tropical sprue, cystic fibrosis, and short bowel syndrome. Excessive intake of oral zinc supplements can cause anemia and hematological abnormalities in the absence of occult blood loss.[218,263] The copper deficiency is caused by zinc induction of metallothionein in the intestinal mucosa, which then sequesters dietary copper, blocking its absorption.

Cardiovascular Disease. Animal studies show that severe copper deficiency causes cardiac damage, but the abnormality differs from that seen in human cardiovascular disease. The myocardium is hypertrophied and may rupture in animal models. Coronary artery pressure is decreased, but in human ischemic disease it is increased.[124] The role of copper in human cardiovascular disease is controversial, although much supporting evidence for a positive link with low dietary copper intake has been published.[309]

Epidemiological surveys have also shown that increased plasma copper values are a positive cardiovascular risk factor. A U.S. study of 4400 adult men and women found that those with plasma copper values in the two highest quartiles had the greatest risk of dying from cardiovascular disease.[176] An increase in plasma ceruloplasmin and hence plasma copper may be a nonspecific response to the inflammation of arteries found in arteriosclerosis. It is known that the ceruloplasmin hepatic messenger RNA (mRNA) increases during inflammation and that this is induced by interleukin 6. Insulin is now also known to be involved in the transcriptional regulation of ceruloplasmin synthesis.[199,514]

Toxicity

As mentioned above, Wilson's disease is a genetic disorder of copper metabolism that causes an increase in copper to toxic levels.[152,203] The problems of diagnosis and appropriate laboratory investigations have been reviewed.[159,192]

The incidence of Wilson's disease is estimated to be 1/30,000 live births with a carrier frequency of 1/90 in the general population. The presentation is highly variable, so adolescents or young adults with otherwise unexplained liver disease or neurological symptoms should be screened, especially where there is a family history of suspected Wilson's disease. Initial local investigations would include plasma copper and ceruloplasmin, which will usually be low (less than 50 μg/dL, 8 μmol Cu per L, and less than 200 mg/L ceruloplasmin). Although the total plasma copper is decreased, the nonceruloplasmin bound fraction is increased, allowing deposition of copper in the brain, eyes, and kidneys.

Slit lamp eye examination may detect copper deposits in the eye (Kayser-Fleischer rings) and there may be abnormalities in liver function tests with an increased urine copper output (>500 μg Cu per L). Liver biopsy for copper analysis is useful in suspected cases and results above 250 μg/g Cu dry weight are usually found (normal 8 to 40 μg Cu per g dry weight). Failure of copper incorporation into plasma ceruloplasmin can also be demonstrated using an oral dose of stable ^{65}Cu isotope.[354] This may be helpful in excluding Wilson's disease when other tests are equivocal. Gene tracking and mutation detection are now possible, but since several hundred mutations exist this may not be informative.

Diagnosis can be difficult in the Wilson's disease cases presenting with acute liver failure.[490,544] Prompt diagnosis is important since urgent liver transplantation may be required.[498] In these cases, a greatly increased plasma copper will be found but without an appropriately increased ceruloplasmin. The unbound plasma copper fraction can increase to more than 80% of the total plasma copper (normal 5% to 10%). The excess copper is released from the necrotic liver and causes intravascular hemolysis and renal failure.[429]

The chronic form of Wilson's disease is treated by oral chelating agents, such as penicillamine and trientine, that remove excess copper from tissue and increase urine copper excretion.[609] Oral administration of zinc salts or ammonium molybdate, which block copper intestinal absorption, has also been successful.[73]

Toxicity can also arise directly from copper contamination of diet and water supplies. Acute poisoning has been recorded following accidental or intentional ingestion of copper sulfate. Guidelines for the maximum copper content of drinking water have been suggested and they vary from about 1 to 3 mg Cu per L. Children may be genetically sensitive to copper in drinking water and develop chronic liver disease,[405] as is found in Indian children exposed to a copper-contaminated diet.[557] Environmental aspects of copper toxicity and the impact upon human health have been reviewed.[147,169]

Laboratory Assessment of Status

Several well-controlled dietary deprivation studies have demonstrated the utility of the clinical laboratory in providing measures of copper status. For example, plasma copper and ceruloplasmin assays are convenient and widely used to confirm severe copper deficiency. However, they are not sensitive indicators in marginal copper depletion.

Since about 90% of plasma copper is bound to ceruloplasmin, factors that increase the hepatic synthesis of ceruloplasmin, such as an APR or the oral contraceptive pill, will increase plasma copper independently of dietary copper intake.[199] In premature infants with liver immaturity and low ceruloplasmin synthesis, plasma copper values below 30 μg/L (<5 μmol Cu per L) suggest the necessity for increased copper input.

Dietary depletion studies using low copper diets have demonstrated a decrease in plasma copper and then a return upon dietary supplementation; however, plasma copper values remained largely within the reference interval.[580] It is suggested that the ratio of immunologically to enzymatically measured ceruloplasmin may be a useful index of marginal copper depletion. This ratio, which is the specific activity of ceruloplasmin, will be low in marginal copper depletion. Apoceruloplasmin increases in blood serum during copper depletion and this will contribute to the total ceruloplasmin assay. The enzymatic activity decreases even in marginal copper depletion. The specific activity of ceruloplasmin is therefore sensitive to copper status and is not affected by age, sex, or hormonal influences.[390] In a study of copper depletion, a low copper diet (0.57 mg/day) was fed to 12 post menopausal women for 35 days followed by supplementation for 35 days (2 mg/day).[391] Responsive markers were red

cell SOD, platelet cytochrome oxidase, red cell glutathione peroxidase, and clotting factor VIII. Although of potential value for detecting marginal copper depletion, these measurements are not in widespread use because of sample instability and lack of standardized methods.[390]

Urine copper decreases during dietary deprivation, but the change from an already low basal value is small, and difficulties in reliable collection and with sample contamination make this of limited use.

Clinically, copper status should therefore be investigated initially by measurement of serum copper and assessment of the APR and interpreted in the light of clinical and drug information.

Reference Intervals

For adults plasma copper is usually in the interval 70 to 140 μg/dL (10 to 22 μmol/L). Values in women of childbearing age and especially in pregnancy are higher. For adults a plasma copper below 50 μg/dL (8 μmo/L) and for infants below 30 μg/dL (5 μmol/L) indicates probable copper depletion. Urine copper output is normally less than 60 μg/24 hr (<1.0 μmol/24 hr) and values above 200 μg/24 hr (3 μmo/L) are found in Wilson's disease. A copper concentration in a liver biopsy sample of >250 μg Cu per g dry weight (normally 8 to 40 μg/g dry weight) is indicative of Wilson's disease, in the absence of other causes of cholestatic disease.

Manganese

Manganese (Mn) is present in biological systems bound to protein in either the 2^+ or 3^+ valence state. It is associated mainly with the formation of connective and bony tissue, with growth and reproductive functions, and with carbohydrate and lipid metabolism.

Chemistry

Manganese (atomic number 25, atomic weight 54.94) is a first transition series metal ($3d^5s^2$) and is next to iron in the periodic table. Of the 11 oxidation states available chemically to manganese, only Mn^{2+} and Mn^{3+} are found in biological systems, mostly bound to protein. The Mn^{2+} ion with an unpaired electron is paramagnetic and can be detected in tissue by magnetic resonance imaging. The bioinorganic chemistry of manganese is complex and detailed accounts have been published.[180,322]

Dietary Sources

Manganese-rich sources include whole grain foods, nuts, leafy vegetables, soy products, and teas. Average intake in the United States is about 2 mg/day, with median values for adult men being 2.2 mg/day, range 0.3 to 8.3 mg/day; and for women median 1.8 mg/day, range 0.3 to 5.9 mg/day (NHANES III). Vegetarian diets containing high amounts of whole grains and nuts can supply more than 10 mg/day.[174]

Absorption, Transport, Metabolism, and Excretion

Dietary manganese is absorbed from the small intestine by mechanisms that may have a pathway common to that of iron. Manganese absorption increases at low dietary intakes and decreases at higher intakes, with tracer studies suggesting absorption efficiencies of 2% to 15%. Diets high in iron, calcium, magnesium, phosphates, fiber, phytic acid, oxalate, and tannins from tea can reduce the absorption of manganese.

Once absorbed, manganese is transported in portal blood to the liver bound to albumin and then exported to other tissue bound to transferrin and possibly to α_2 macroglobulin. Excretion of manganese is primarily via bile into feces, with urine output being very low and not sensitive to dietary intake.[322]

Functions

Manganese is a constituent of many important metalloenzymes and also acts as a nonspecific enzyme activator. Mn^{2+} ions can be replaced by Mg^{2+}, Co^{2+}, and other cations during the activation of some enzymes.[322] Some important manganese-dependent enzymes are discussed below.

Superoxide Dismutase (SOD). Manganese-dependent SOD is a mitochondrial enzyme and is an important factor in limiting oxygen toxicity; it is one of the most studied enzymes in human biochemistry. The enzyme catalyzes the breakdown of the superoxide radical O_2^- to H_2O_2, which is then removed by catalase and glutathione peroxidase. The half-life of this enzyme in blood serum is longer than that of the cytoplasmic Cu, Zn SOD.

Pyruvate Carboxylase. This enzyme has manganese firmly in its structure and acts together with phosphoenol pyruvate (PEP) carboxykinase, an enzyme that is activated by manganese ions. These enzymes are required to catalyze the formation of PEP from pyruvate, a key reaction in the hepatic synthesis of glucose.

Arginase. Arginase is the terminal enzyme in the urea cycle, hydrolyzing L-arginine to urea and ornithine, completing the deamination of amino acids. Arginase is most concentrated in the liver, but is also found in other tissues. The structure of the enzyme isolated from rat liver shows it to have a unique binuclear manganese cluster.[296] The activity of arginase affects the production of nitric oxide by limiting the availability of L-arginine required for the synthesis of nitric oxide synthetase. This relationship has been investigated in a number of diverse diseases, including asthma and schizophrenia.[383,630]

Glycosyl Transferases. These enzymes are responsible for the sequential addition of carbohydrate molecules to proteins to form proteoglycans, and ultimately connective tissue and cartilage. They are therefore important for the structural integrity of bone and skin, and for normal wound healing.

Requirements and Reference Nutrient Intakes

Because of lack of information on manganese dietary requirements, the Food and Nutrition Board has set an AI level for adults at 2.3 mg/day for males and 1.8 mg/day for females. A tolerable upper intake limit of 11 mg/day was set for adults based on no observed effect for

Western diets. For infants the UL could not be set because of lack of data. There is concern about the potential toxicity of manganese for infants whose immature hepatic development reduces the biliary excretion of excess manganese. Therefore, the only dietary source of manganese in the age group 0 to 12 months should be from normal diet or from a formula.[174]

Deficiency

Overt manganese deficiency has not been documented in humans eating natural diets. However, in numerous animal studies, signs of experimentally induced manganese deficiency include impaired growth and reproductive function, skeletal abnormalities, impaired glucose tolerance, and impaired cholesterol synthesis.[322] A child on long-term TPN lacking in manganese developed signs of bone demineralization and impaired growth that were reversed by supplementation.[422] A volunteer male was deprived of vitamin K and inadvertently of manganese when fed a diet with only 0.34 mg Mn per day for 6.5 months. Effects included a low plasma cholesterol, dermatitis, color changes in hair, and reduced blood-clotting function not responsive to vitamin K. Supplementation with manganese gradually reversed these symptoms.[137] Seven young men fed experimental diets low in manganese developed skin lesions and low plasma cholesterol.[185]

Prolidase deficiency in infants is a rare genetic disorder that causes (1) skin ulceration, (2) mental retardation, (3) increased urinary excretion of iminodipeptides, (4) recurrent infections, and (5) splenomegaly; it is known to be associated with abnormalities of manganese biochemistry. Red cells have an increased amount of manganese although serum manganese is normal. Red cell arginase activity is less than half of normal, suggesting a defect in the supply of manganese for enzyme activation.[343,346]

Various unrelated medical conditions have been observed to be associated with lowered serum or whole blood manganese. These include osteoporosis, diabetes mellitus, and epilepsy.[247] The clinical relevance of such observations is uncertain.

Toxicity

The occupational health hazard from prolonged exposure to manganese-containing dust or fumes is well recognized (see Chapter 35). Neurological symptoms resembling Parkinson's disease develop slowly over a period of months or years. The health risks from long-term, low-level manganese exposure have been reviewed.[208]

Of concern is the possibility that patients with severe liver disease may have neurological and behavioral signs of manganese neurotoxicity because of failure to excrete manganese in bile. Manganese deposition in the globus pallidus during liver failure results in T_1-weighted magnetic resonance signal hypersensitivity. By causing deficits in neurotransmitter production, manganese ions may be partially responsible for the symptoms of postsystemic hepatic encephalopathy.[238] Deposition of manganese in the brain has been demonstrated in children with biliary atresia[264] and in adult cirrhotic patients.[541]

Patients receiving manganese intravenously during TPN have also shown evidence of manganese retention and deposition in the midbrain and brainstem, especially those with cholestasis. Typical symptoms are of a parkinsonian-like tremor and abnormalities of gait.[144] Children have also been observed to accumulate manganese in the globus pallidus and brainstem, although with nonspecific symptoms.[433] A study on adults compared the effects of increasing doses of manganese of 0, 1, 2, and 20 μmol/day in patients receiving home parenteral nutrition.[554] A high correlation was found between blood manganese, magnetic resonance imaging (MRI) intensity, and T_1 values in the globus pallidus. A dose of 1 μmol/day (55 μg/day) caused no abnormalities in MRI measurements and blood manganese remained within the reference interval.

In a study of 30 patients receiving long-term home IV nutrition, whole blood manganese was increased (>3.8 μg/L, 210 nmo/L) in 26 patients and plasma manganese in 23 (>4 μg/L, 23 nmol/L) patients. None of the patients had signs of neurological disease. In a control group of patients with cholestatic disease, but not receiving IVN, whole blood manganese was within the reference interval.[611] This suggests that cholestasis alone will not lead to increased blood manganese, and the main reason for high blood concentrations in patients on IV nutrition is excess provision, with this being made worse if cholestasis also exists. Infants (0 to 12 months) requiring IVN are at particular risk because of immature hepatic function. In a group of 57 children receiving IVN,[154] 11 had both cholestasis and increased blood manganese and one had a movement disorder. Four of these 11 patients died and whole blood manganese was very high (11 to 33.5 μg/L, 615 to 1840 nmol/L) in the 7 survivors. Manganese supplements were reduced or withdrawn, and after 4 months blood manganese had declined to 11.6 μg/L (643 nmol/L). During the same period, serum bilirubin also declined significantly. The long-term outcome of manganese deposition has been investigated in two children on long-term TPN who initially had MRI scan abnormalities and raised whole blood manganese.[290] After reduction of manganese input, they were followed for a 3-year period with improvement in MRI scan abnormalities and a fall in whole blood manganese. No neurological signs were found, and the children developed normally. It is now recommended that only 1 μg Mn per kg (18 nmol/kg) be administered during TPN in infants and no more than 1 to 2 μmol/day (55 to 110 μg/day) in adults.

All patients requiring prolonged IVN, especially those who have cholestasis, should be monitored for evidence of manganese retention.

Laboratory Assessment of Status

There is a necessity to balance the need for adequate manganese nutrition against the potential risk from toxicity.[208] This necessitates monitoring of manganese status in at-risk patients. Whole blood manganese levels are not responsive to dietary depletion, but measurement of serum manganese,

lymphocyte Mn SOD activity, and blood arginase are potentially useful when assessing possible nutritional depletion, although these are rarely performed in clinical practice. Whole blood manganese and serum manganese in combination with brain MRI scans and neurological assessment are used to detect excessive exposure. Manganese in whole blood and plasma or serum is determined by standard graphite furnace AAS methods.[390,435]

Plastic cannulae should be used for phlebotomy, and hemolysis should be prevented during sample separation. Whole blood has about 10 times as much manganese as plasma or serum and is not as affected by contamination from steel needles during sample collection. This makes measurement of whole blood manganese the most widely used method in clinical laboratory practice for monitoring manganese status.

Reference Intervals

The reference interval for serum manganese is 0.5 to 1.3 µg/L (9 to 24 nmol/L). The reference interval for whole blood manganese is 5 to 15 µg/L (90 to 270 nmol/L). Increases in serum manganese to >5.4 µg/L (>30 nmol/L) or blood manganese to >20 µg/L (>360 nmol/L) are indices of manganese retention.

Molybdenum

The essential need for molybdenum (Mo) by animals and humans is based on its incorporation into metalloenzymes.

Chemistry

Molybdenum (atomic number 42, atomic weight 95.94) is a metal in the second transition series. The element can have a number of oxidation states but the most stable in biological systems is Mo^{6+} as found in molybdate (MoO_4^{2-}). Molybdenum has the highest atomic number of the essential trace metals. There is a close parallel between molybdenum, tungsten, and vanadium chemistry. Molybdenum enzymes are ecologically vital, facilitating important carbon, nitrogen, and sulfur cycles.[180]

Dietary Sources

Legumes, such as peas, lentils, and beans, are good sources along with grains and nuts, whereas meats, fruits, and many vegetables are relatively poor sources.[174] The average dietary intake is 76 to 109 µg Mo per day for U.S. adults.

Absorption, Transport, Metabolism, and Excretion

Molybdenum is efficiently absorbed over a wide range of dietary intakes mainly as molybdate, although competitive inhibition of absorption by sulfate reduces intestinal uptake. Concentrations in whole blood are about 1.0 µg/L (10 nmol/L) and some 80% to 90% or more of molybdenum in whole blood is bound to red cell proteins. Transport of the smaller amount in blood plasma may involve α_2-macroglobulin.[174] Urine output directly reflects the dietary intake of molybdenum, stable isotope studies at high and low levels of intake indicating renal homeostatic regulation.[579,616]

Functions

Several important mammalian enzymes, such as sulfite oxidase, xanthine dehydrogenase, and aldehyde oxidase, require molybdenum as a cofactor. This organic component is a molybdopterin complex.[307] Sulfite oxidase is probably the most important enzyme in relation to human health. This enzyme catalyzes the last step in the degradation of sulfur amino acids, oxidizing sulfite to sulfate and transferring electrons to cytochrome c. Xanthine dehydrogenase and aldehyde oxidase hydroxylate a number of heterocyclic substances, such as purines, pteridines, and others.[287]

Requirements and Reference Nutrient Intakes

The RDA for Mo has been set at 45 µg Mo per day for adults, which is below the estimated average dietary intake.[174]

Deficiency

Molybdenum deficiency has not been observed in healthy people consuming a normal diet. A single case report[3] described a patient receiving prolonged parenteral nutrition during treatment for severe Crohn's disease who developed an intolerance to intravenous amino acids, especially L-methionine. Clinical signs included tachycardia, visual defects, neurological irritability, and eventually coma. The symptoms improved on discontinuing amino acid infusion. Biochemical abnormalities included high plasma methionine and low plasma uric acid levels. There was an increased urinary sulfite, thiosulfate, and other abnormalities of urinary sulfur output, with a low excretion of uric acid and xanthine metabolites, suggesting defects in sulfite oxidase and xanthine oxidase. Treatment with ammonium molybdate (300 µg/day) improved the clinical and biochemical abnormalities.

The lack of further reports of this nature suggests that for most patients there is sufficient molybdenum present as a contaminant in the TPN fluids. Nonetheless, it is now common to include a small amount of molybdenum (19 µg/day, 0.2 µmol/day) in trace element additive mixtures.

There are also very rare recessive inherited diseases that result from defects in the biosynthesis of molybdenum cofactor; in most cases they result in early childhood death. First symptoms are failure to thrive and seizures; in later stages lens dislocations are noted together with cerebral atrophy. Disease-causing mutations have been located, and the possibility of gene therapy is being investigated.[461,462]

Biochemical diagnosis can be made by detection of excess sulfite in urine using the Merckoquant sulfite dipstick test (Merck KGaA, Darmstadt, Germany). Samples should not be evaluated until at least 10 days after birth and should be tested within 10 minutes of collection. Another type of molybdenum cofactor deficiency can be confirmed by finding a low plasma uric acid. Specialized centers

can offer biochemical prenatal diagnosis on chorionic villi samples.[307]

Toxicity

Molybdenum compounds have low toxicity in humans. There are some reports of increased blood uric acid in occupational exposures and also in Armenian populations that have an abnormally high dietary intake (10 to 15 mg Mo per day). A single report of acute toxicity from self-administration of 300 to 800 μg Mo per day was not confirmed by later studies on healthy men given as much as 1500 μg Mo per day for 24 days.[247]

Excess molybdenum intake induces copper deficiency in ruminants by blockading copper absorption through formation of an insoluble thiomolybdate-copper complex. This has suggested the use of ammonium molybdate in the management of Wilson's disease.[73] There is also speculation that the blockade of copper absorption using molybdate may influence new blood vessel formation (angiogenesis) during tumor growth.[72]

Laboratory Assessment of Status

Whole blood and serum or plasma molybdenum concentrations are too low to be used for the detection of deficiency. However, urinary output is responsive to increases or decreases of input. Measuring urate or sulfite in the urine is the most available means of confirming molybdenum cofactor disorders or possible molybdenum deficiency by detecting changes in sulfur and purine metabolism. Until recently only neutron activation analysis (NAA) had sufficient sensitivity to measure molybdenum in biological samples.[602] With the availability of ICP-MS, studies using stable molybdenum isotopes are now possible, and this has been used to investigate absorption and excretion of molybdenum during depletion and repletion studies.[579]

Reference Intervals

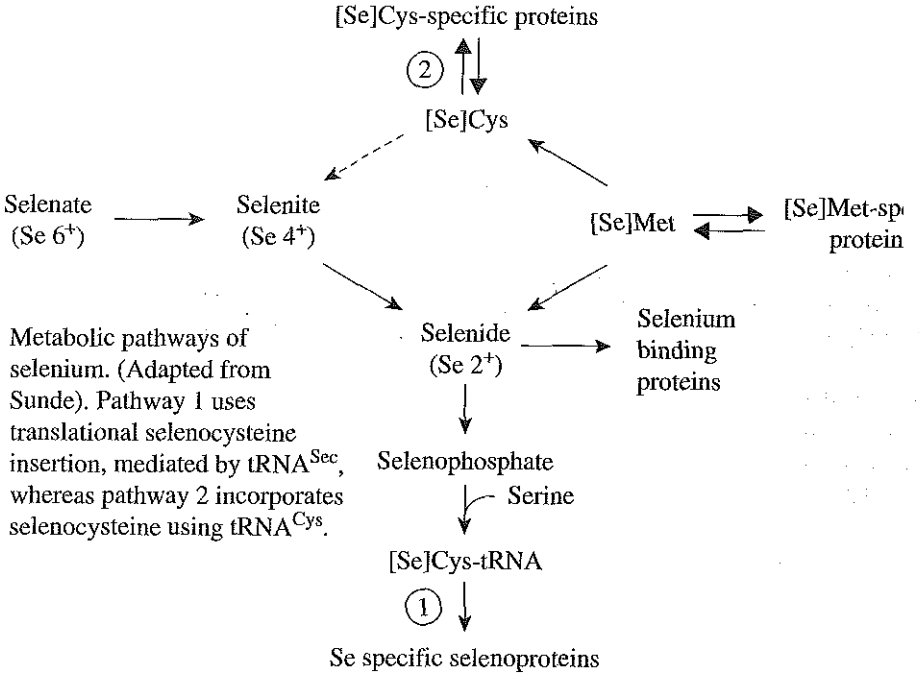
There is about 0.5 μg Mo per L (5 nmol/L) in plasma or serum and about 1 μg Mo per L (10 nmol/L) in whole blood.[602] Urine molybdenum values determined by ICP-MS vary from 40 to 60 μg/L, the amount determined being influenced by recent dietary intake.[271]

Selenium

Selenium (Se) is an essential element for humans, being a constituent of the enzyme glutathione peroxidase and believed to be closely associated with vitamin E in its functions.

Chemistry

Selenium (atomic number 34, atomic weight 78.96) is a nonmetal and has several chemical forms and valences. Selenium is in group VI of the periodic table, and therefore it has a bioinorganic chemistry that is related to sulfur.[180,550] The most important biologically active compounds contain selenocysteine, where selenium is substituted for sulfur in cysteine. Now considered to be the twenty-first amino acid, selenocysteine is incorporated into proteins by the specific codon UGA, which was previously thought to be solely a stop codon.[236] Selenomethionine is synthesized by plants but not in animals or humans. Since it is biologically identical to methionine sharing the same metabolic pathways, selenomethionine is nonspecifically incorporated into the general protein pool and is present in major proteins, such as albumin and hemoglobin. Selenium in selenomethionine makes up about half of the total dietary intake and is made available for selenocysteine synthesis when the methionine pathways catabolize selenomethionine. Ingested selenium compounds selenate, selenite, selenocysteine, and selenomethionine are metabolized largely via selenide that may be associated with a chaperone protein before being converted to selenophosphate, which is an important precursor in the synthesis of selenocysteine proteins (Figure 30-27).[550]



Dietary Sources

Selenium enters the food chain mainly as selenomethionine from plants that take the element up from the soil but do not appear to use it. The soil content of selenium is highly variable and can be low in volcanic soils when soluble salts are leached out by ground water. Soils in parts of China and New Zealand are particularly low in selenium. Acid soils, where insoluble selenium complexes can be formed with iron and aluminum, occur in some parts of Europe, resulting in low available soil selenium. The geographical source of plant and animal foodstuffs determines the level of dietary intake. In the United States and Canada, wheat and other cereal products are a good source of selenium; average intakes in North America range from 80 to 220 μg Se per day, whereas in the UK dietary intake is about 30 to 60 μg/day.[30] Intakes in China are as low as 11 μg/day and in New Zealand 28 μg/day.[84]

Absorption, Transport, Metabolism, and Excretion

Intestinal absorption of the various dietary forms of selenium is efficient but is not regulated. The inorganic salts selenite and selenate used as dietary supplements and in food fortification are almost completely absorbed, but much of the selenate ion is rapidly excreted in urine.[179a] Selenium from inorganic salts is more rapidly incorporated into glutathione peroxidase and other selenoproteins than selenium from organic sources containing selenomethionine. However, selenium-enriched yeast containing the organic forms is considered less toxic and is widely used as a dietary supplement.[172]

Whole body selenium is about 15 mg, as estimated by direct tissue analysis and radioisotope techniques, with the tissue concentration of selenium being highest in the kidney and the liver followed by the other organs. Radioisotope-labeled selenium accumulates initially in the liver, kidneys, and lungs. Selenium present in some selenocysteine proteins appears to be a functional reserve. When dietary selenium is limited, synthesis of glutathione peroxidase (GSHP)x-1 is

Metabolic pathways of selenium. (Adapted from Sunde). Pathway 1 uses translational selenocysteine insertion, mediated by $tRNA^{Sec}$, whereas pathway 2 incorporates selenocysteine using $tRNA^{Cys}$.

Figure 30-27 Metabolic pathways of selenium.

down regulated, making selenium available for synthesis of other proteins.[172]

The concentrations of selenium in whole blood and in plasma and/or serum are related to dietary intake. About 50% to 60% of the total plasma selenium is present as the protein selenoprotein P, a highly basic protein having multiple histidine residues and about 10 atoms of selenium per molecule.[550] Around 30% of plasma selenium is present as glutathione peroxidase (GSHPx-3) and the remainder is incorporated into albumin as selenomethionine.[234]

Urinary output of selenium is the major route of excretion and reflects recent dietary intake. The amounts excreted vary widely ranging from less than 20 µg Se per L to above 1000 µg Se per L, depending upon the geographical origins of the food.[6]

Functions

Thirty or more biologically active selenocysteine-containing proteins are now identified. More than 15 have been purified and their biological function investigated.[79,550] Some of the most important ones are listed below.

Glutathione Peroxidase (GSHPx). This enzyme has four isoforms, GSHPx-1 in red cells, GSHPx-2 in gastrointestinal mucosa, blood plasma GSHPx-3, and the cell membrane located GSHPx-4. These enzymes use the reducing power of glutathione to remove an oxygen atom from hydrogen peroxide and lipid hydroperoxides. They may also be involved in regulation and formation of arachidonic metabolites derived from hydroperoxides.[18]

Iodothyronine Deiodinase. Type I, II, and III isoforms of this enzyme are responsible for conversion of the precursor hormone T_4 to the active hormone T_3.[79] Type I, thyroxine-5-deiodinase, is located in the liver, kidney, and muscle and is responsible for more than 90% of plasma T_3 production. Pituitary, brain, and brown adipose tissue contain the Type II and III deiodinases.[550]

Thioredoxin Reductases. Three isoforms catalyze the NADPH-dependent reduction of thioredoxin and are important in maintaining the intracellular redox state.

Selenophosphate Synthetase. This enzyme is required for the intracellular synthesis of selenoproteins via a monoselenium phosphate intermediate.

Selenoprotein P. This protein is the major selenium-containing protein in blood plasma, may be a transport protein for the element, and has an antioxidant function.[85]

Selenoprotein W. This is a selenoprotein found in skeletal muscle that is reduced in concentration in white muscle disease in animals.[550] Deficiencies in the production of these selenoproteins, especially the glutathione peroxidases, are likely to be related to signs and symptoms of selenium deficiency disease.

Requirements and Reference Nutrient Intakes

It is now proposed,[172] after review of Chinese and New Zealand supplementation studies, that the RDA for selenium is set at 55 µg/day for adults. On this basis, dietary surveys in North America do not indicate that selenium deficiency is likely in the general population. However, in many countries in Europe, intakes are now close to or below 55 µg/day, and selenium dietary provision may now be suboptimal.[458]

Intravenous Supply

There is uncertainty about the most appropriate intake, but given the above figures for dietary requirement, intra-

venous requirement is unlikely to be less than 40 μg/day (0.5 μmol/day), and in many adult patients, especially the more seriously ill, it may be 100 μg/day (1.3 μmol/day) or more.

Deficiency

The role of selenium in human medicine has been reviewed.[84,458] Animal studies in the 1950s demonstrated the nutritionally beneficial effects of selenium by showing that there was a selenium-responsive liver necrosis in vitamin E–deficient rats. There are important selenium-dependent diseases in farm animals, such as white muscle disease in sheep and cattle, and myopathy of cardiac and skeletal muscle in lambs and calves. In these animals, some cause of oxidative stress, such as increased physical activity or vitamin E deficiency—together with dietary selenium deficiency—is required to elicit the disease.

Severe Deficiency. Symptomatic selenium deficiency has been well characterized in Keshan disease and nutritional depletion in hospital patients.

Keshan Disease. Conclusive evidence for a role for selenium in human nutrition came with publication of the results of large-scale trials in China that show the protective effect of selenium supplementation on children and young adults suffering from an endemic cardiomyopathy. This was observed in areas of the country (Keshan region) with low soil selenium levels.[550]

Kashin-Beck Disease. A type of severe arthritis is described in parts of China and neighboring areas of Russia where soil selenium is particularly low. However, trials of selenium supplementation were not conclusive and other unidentified factors may be present.

Nutritional Depletion in Hospital Patients. Selenium was one of the last essential trace elements to be accepted as nutritionally important, with more attention being given to its potential toxicity. There was initially inadequate selenium provision in specialized diets used to treat inborn errors[590] and during long-term parenteral nutrition,[594] leading to cases of deficiency. Symptomatic cases continue to be reported, although the need for selenium supplementation during nutritional support is well established. Symptoms of severe deficiency include muscle weakness.[302] Cases involving cardiomyopathy, which is usually fatal and resembles Keshan disease,[340,633] and macrocytosis and pseudoalbinism in children[605] have been described.

Marginal Deficiencies. Marginal selenium deficiencies are thought to be involved in thyroid function, immune function, reproductive disorders, mood disorders, inflammatory conditions, cardiovascular disease, viral virulence, and cancer chemoprevention.

Thyroid Function. Selenium and other trace elements are necessary for normal thyroid function since the important deiodinase enzymes are selenoproteins.[19] Three children with biochemical and clinical signs of hypothyroidism were successfully treated by oral selenium therapy.[442] Although the deiodinases are not thought to be significantly affected in marginal selenium depletion, it has been observed that endemic goiter in Sri Lanka, which is resistant to iodine supplementation, occurs in areas with low soil selenium.[177] Similarly, endemic thyroid disease in Zaire may be related to the combination of iodine and selenium depletion. Care must be taken since the stimulation of thyroid hormone metabolism may induce hypothyroidism.

The low T_3 syndrome observed after major trauma may also be related to changes in selenium status affecting the activity of iodothyronine deiodinase, with selenium supplements reversing most of the biochemical abnormalities found in thyroid function tests.[46]

Immune Function. Deficiency of selenium is accompanied by loss of immunocompetence and this is related to the reduction of selenoproteins in the liver, spleen, and lymph nodes. Both cell-mediated immunity and B-cell function are impaired.

Considerable selenium losses in wound exudates following severe burns have been recorded, and supplementation of a mixture of selenium, zinc, and copper leads to a reduction in respiratory infections.[47] Supplementation, even in apparently selenium-adequate individuals, has some immune function stimulatory effects, including improvement in natural killer cell activity and increases in IL-2 receptor expression.[458] It has been speculated that the increased infection rates in acquired immunodeficiency syndrome (AIDS) patients may be related to selenium depletion and this may even influence the progression from human immunodeficiency virus (HIV) positivity to the AIDS syndrome.[34]

Reproductive Disorders. Adequate selenium supply is necessary for successful reproduction in a variety of farm animals. Various studies have looked at the situation in humans. Male fertility could be affected by selenium depletion insofar as it is necessary for testosterone synthesis and to maintain sperm viability.[458]

Mood Disorders. The brain is reported to receive a priority supply of selenium during dietary depletion and/or repletion studies in animals and the turnover of neurotransmitters is altered. This has led to extensive studies of the role of selenium and other antioxidants in senility of the elderly, in epilepsy in children, and in Alzheimer's disease. Marginal selenium depletion has been associated with anxiety, confusion, and hostility, and improvements have been claimed following supplementation.[458]

Inflammatory Conditions. Many conditions associated with inflammation and increased oxidative stress could be influenced by selenium status.[16] Positive effects from supplementation studies in arthritis and in pancreatitis have been reported. Low serum selenium values are found in asthma, and some limited clinical trial studies show benefits from supplementation.[458] In a small trial in patients in intensive care with systemic inflammatory response syndrome (SIRS), high-dose selenium supplements over 9 days were associated with reduced incidence of renal failure and reduced mortality in the most severely ill.[16]

Cardiovascular Disease. The protective role of selenium against cardiovascular disease has been extensively investigated, but with no conclusive findings.[165,458] The low soil selenium concentration in Finland resulted in locally grown food having low selenium content. This together with concerns about the high incidence of coronary disease in parts of the country led to selenium fortification of agricultural fertilizers.[312] Although an impressive decline in coronary disease mortality was found between 1972 and 1992, the benefits were linked primarily to other major diet and lifestyle changes.[440]

Viral Virulence. It is now considered possible that an unusually virulent strain of the Coxsackie virus is part of the cause of cardiomyopathy in selenium-depleted regions of China. This is consistent with the marked seasonal variations in the incidence of the disease.

It is known that nutritional depletion will impair the immune responses and increase the lethalness of viruses and other infectious agents. A series of experimental studies on mice have shown that a nonlethal form of Coxsackie B (CVB 3/O) converted to a virulent strain when inoculated into selenium-deficient mice.[39] Inoculation of selenium-adequate mice with the mutated virus then caused myocarditis. Sequencing the DNA from the altered virus showed that there were 6 nucleotide changes that corresponded to nucleotide sequences in the genome of a virulent strain of the virus. Further evidence came from experiments with GSPHx knockout mice. More than half of these mice infected with the nonlethal CVB/3O virus developed myocarditis but none of the wild type controls were affected. The virus recovered from these affected mice showed genome changes similar to those found in virulent strains of the virus. It is thought that the selenium-deficient host altered the viral pathogen, probably involving oxidative stress in the tissue of the depleted animals. Further animal studies[38] have demonstrated that a mild strain of influenza virus exhibits increased virulence when given to selenium-deficient mice. New viruses continue to appear through the evolution of existing viruses and these may be lethal strains. RNA viruses are known to mutate easily and lack proofreading systems and repair mechanisms.[37,330,415]

There is speculation that a similar process can occur in regions of the world, such as parts of Africa, where the human population has depletions of selenium and other micronutrients and is intermittently exposed to viral diseases. There is as yet no direct evidence that similar processes do occur in human populations. However, an epidemic of optic and peripheral neuropathy in Cuba that affected more than 50,000 individuals was shown to be associated with deficiencies of several micronutrients, including selenium. Supplementation of the population with a multicomponent micronutrient mixture coincided with the subsidence of the disease.[37]

Cancer Chemoprevention. Although not primarily a nutritional issue, there is interest in the role of selenium supplementation in the prevention of certain types of cancer. Experimental work on animals shows that chemical carcinogenesis is modified by selenium. Also, epidemiological surveys have found a link between cancer incidence and soil selenium content, suggesting a higher incidence of certain cancers in individuals with a low selenium intake.[116] Large-scale trials in China, conducted on more than 130,000 individuals, compared one township (20,847 people) having a high risk for viral hepatitis B and liver cancer with four control townships in the same area. The high-risk population received selenium-enriched table salt and in an 8-year follow-up the average incidence of liver cancer was reduced by 35%. There was no reduction in incidence in the control populations. Studies on 226 people with chronic hepatitis B found that a controlled trial of selenium-enriched yeast reduced the development of liver cancer during a 2-year follow-up period.[632]

It now seems likely that selenium supplementation above the minimum dietary requirement has a role in cancer prevention, particularly in relation to prostatic cancer.[110] The mechanism is not established, but in selenium-adequate subjects the excess selenium may produce a low molecular weight methylated selenium compound that has chemopreventive properties.[115,116] A large selenium and vitamin E cancer prevention study, known as the Selenium and Vitamin E Cancer Prevention Trial (SELECT) study, will carry out controlled trials on more than 32,000 men to establish if there is a beneficial effect.[308]

Toxicity

Areas of China and the United States have high amounts of selenium in soil, and locally produced food contains excess selenium. Clinical signs of selenosis are garlic odor in the breath, hair loss, and nail damage.[172] The tolerable upper limit has been set at 400 µg/day for adults and less for children. There have been reported cases of toxicity from self-administered dosages. Because of a manufacturing error, 13 individuals taking supplements containing 27.3 mg (27,300 µg) per tablet showed clinically significant selenium toxicity.[247]

Laboratory Assessment of Status

Early animal studies and human population surveys used whole blood as the main indicator of selenium status. Whole blood selenium can be determined after acid digestion using a fluorometric method.[235] The more convenient carbon furnace atomic absorption spectroscopy (CFAAS) assay for plasma and/or serum selenium is now the most widely used procedure.[194] The main components of plasma selenium are extracellular glutathione peroxidase (GSHPx-3) and selenoprotein P.

Red cell GSPHx-1 and plasma GSPHx-3 are assayed by enzymatic methods using a variety of peroxide substrates,[550] with tertiary-butyl peroxide being a commonly used substrate since it is not as affected by catalase as is hydrogen peroxide.[51] The values obtained are dependent on the substrate used and the reaction conditions. During selenium supple-

mentation studies, the plateau reached in plasma GSPHx-3 activity has been used to assess minimum dietary requirements.[172]

The effects of different forms of inorganic and organic selenium supplementation upon GSPHx activity in blood lymphocytes, granulocytes, platelets, and erythrocytes have been described in a trial on 45 human volunteers.[80] Some changes were acute and transient, whereas cytosolic GSHPx activity (GSHPx-1) increased gradually in both treatment groups over 28 days.

In patients receiving TPN at home, the time course for development of deficiency and repletion of enzyme activity has been studied.[113] After 1 year on TPN without selenium supplements, all patients had low plasma selenium and red cell GSHPx, and cellular metabolism of exogenous hydrogen peroxide was also impaired. With replacement of selenium as selenious acid, there was a rapid increase in GSHPx-3 within the first 24 hours, reaching normal levels within 1 to 2 weeks. Platelet GSHPx also returned to normal in 1 to 2 weeks, whereas polymorph GSHPx was more variable but normalized in about 3 weeks. Red cell GSHPx took 3 to 4 months to recover, consistent with the need for formation of these cells in the presence of selenium.

The major selenium-containing plasma protein selenoprotein P can be determined by immunological methods.[5] The production of monoclonal antibodies to selenoprotein P has been described[489] and used to study the structure and function of the protein and to quantify it. It is also possible to separate selenoprotein P from other plasma proteins by heparin affinity chromatography followed by CFAAS selenium analysis.[234] Selenoprotein P concentration in plasma responds rapidly to supplementation and has been used in nutritional studies of Chinese populations to confirm the adequacy of intake.[250]

Plasma selenoprotein P, plasma GSPHx-3, and total plasma selenium concentration are all lowered by the APR to injury or infection.[418] This effect should be considered when interpreting plasma selenium values in postoperative patients or those with infection or inflammatory disease.

Hair and nail selenium analysis can be useful as a measure of long-term dietary selenium intake. Selenium being a sulfur analogue, it is incorporated into the sulfur-rich keratin of hair and nails. One study showed a correlation between toenail selenium, blood selenium, and dietary intake.[344] In a study of a 10-year old child receiving TPN who developed selenium-responsive muscle weakness, hair analysis was used to help assess selenium dosage.[568] An analytical method using microwave-assisted acid digestion of hair and nails, followed by CFAAS selenium analysis, has been described.[233] In a small study using this procedure, values for hair and nail selenium in healthy UK people were found to be 0.32 to 0.76 μg/g (n = 25) and 0.17 to 0.66 μg/g (n = 27), respectively. However, for population studies, use of selenium-containing hair preparations will affect the hair selenium results and this would have to be carefully assessed and controlled.

Urine selenium output is mainly a reflection of the recent dietary input and has not been extensively employed in population surveys.

In summary, there are many possible markers for selenium status. In practice, measurement of plasma selenium or GSHPx provides a good estimate of status and in particular the adequacy of recent intake, provided they are interpreted in the knowledge of changes in the APR. For a better index of long-term intake, platelet, red cell, or neutrophil GSHPx, or hair or nail selenium can also be measured.

Reference Intervals

The reference interval for selenium in whole blood, plasma or serum, hair, and nails should be established locally, since these indices are affected by dietary selenium intake. Plasma selenium adult values lie in the interval 63 to 160 μg/L (0.8 to 2.0 μmol/L). Values of less than 40 μg Se per L (0.5 μmol/L) indicate probable selenium depletion.

Values in children are lower and in the UK are[569] 16 μg/L to 71 μg/L (0.2 to 0.9 μmo/L) for <2-year-olds; 40 μg/L to 103 μg/L (0.5 to 1.3 μmol/L) for 2- to 4-year-olds; and 55 μg/L to 134 μg/L (0.7 to 1.7 μmol/L) for 4- to 16-year-olds. Cut-off values of less than 8 μg/L (0.1 μmol/L) in neonates are strongly suggestive of selenium depletion. Increased plasma values are found in suspected selenium toxicity and results above 5 μmol/ (400 μg/L) are an indication of excess intake.

Red cell glutathione peroxidase activity (GSHPx-1) in adults varies from 13 to 25 U/g Hb, whereas values in children are slightly lower.[569] Local age-related reference intervals are again required.

Zinc

The discovery of a variety of zinc (Zn) related clinical disorders has directly demonstrated the importance of zinc in human nutrition. It is second to iron as the most abundant trace element in the body.

Chemistry

Zinc (atomic number 30, atomic weight 65.39) lies at the end of the first transition series. Zn^{2+} with a filled 3*d* electron shell is a particularly stable ion. The bioinorganic chemical features of zinc, which underlie the very diverse biological functions of this trace metal, include its relatively high abundance compared with other trace elements. Zinc has fast ligand exchange kinetics and flexible coordination geometry, and is a good electron acceptor (strong Lewis acid), with no redox reactions. There is a hypothesis that zinc ions, present in the cytoplasm at 10^{-11} mol/L and in equilibrium with numerous zinc metalloenzymes and transcription factors, can act as a "master hormone," particularly in relation to cell division and growth.[180] There are no naturally colored zinc complexes and this may have delayed the recognition of the biological importance of zinc until the development of suitable atomic spectroscopic methods that could be applied to

biological samples and used as probes to identify and study metalloproteins.[96]

Dietary Sources

Zinc is widely distributed in food mainly bound to proteins. The bioavailability of dietary zinc is dependent upon the digestion of these proteins to release zinc and allow it to bind to peptides, amino acids, phosphate, and other ligands within the intestinal tract. The most available dietary sources of zinc are red meat and fish, whereas white meats and flesh from young animals provide less zinc. Wheat germ and whole bran are good sources but their zinc content is reduced by milling and food processing. The median intake for men in the United States is about 14 mg/day and for women 9 mg/day.[174]

Absorption, Transport, Metabolism, and Excretion

Regulation of the net intestinal uptake of zinc is by control of absorption efficiency in the face of variable dietary zinc input and ranges from 20% to 50% of the dietary content. At an intake of 12.2 mg Zn per day, the fractional absorption was 26%, but at the very low intake of 0.23 mg Zn per day this increased to 100%. These and other measurements were made on 12 male volunteers using stable ^{67}Zn tracer to assess zinc homeostasis and plasma zinc kinetics.[306] Estimates of zinc absorption have also been compared using four different stable isotope techniques.[348] It was concluded that a double isotopic tracer ratio method is accurate and is recommended as a practicable procedure. Using this method, the fraction of dietary zinc absorbed was equivalent to 30% ± 10%. Fine control of net absorption is by secretion of endogenous zinc into the intestinal lumen from pancreatic fluid and other intestinal fluids.[305] Such losses range from less than 1 mg/day on a low zinc diet to more than 5 mg/day on a zinc-rich diet. The ability to conserve dietary zinc by limiting intestinal loss can allow a positive metabolic balance even at low dietary zinc intakes. Interaction with other dietary constituents such as phytate, calcium, and iron reduce, the net absorption of zinc significantly so that diets high in phytate and calcium reduce the growth rate of young rats.

In human diets, leavening of bread and exposure of cereals to wet heat lower the phytate content, increasing zinc availability. Other factors, such as dietary fiber and a constituent of beans, can also lower zinc intestinal absorption but to a lesser extent.[106] Iron at supplemental dosages (up to 65 mg/day) may decrease zinc absorption so that pregnant and lactating women taking iron may require zinc supplementation.[426]

Absorbed zinc is transported to the liver by the portal circulation where active incorporation into metalloenzymes and plasma proteins such as albumin and α_2-macroglobulin occurs. Blood plasma contains less than 1% of the total body content of zinc and lies within a narrow concentration interval 80 to 120 µg/dL (12 to 18 µmol/L). About 80% of plasma zinc is associated with albumin and most of the rest tightly bound in the high molecular protein α_2-macroglobulin.[175] The zinc on albumin is in equilibrium with plasma amino acids (mostly histidine and cysteine) and this small (<1%) ultrafilterable fraction may be important in cellular uptake mechanisms (Figure 30-28).[106]

Total adult body content of zinc is about 2 to 2.5 g and the metal is present in the cells of all metabolically active tissue and organs. About 55% of the total is found in muscle and approximately 30% in bone.[106] The prostate, semen, and the retina have particularly high local concentrations of zinc. Almost all zinc in a red cell is in the form of carbonic anhydrase so that red cell zinc concentration is about 10 times higher than plasma. Hemolysates normally have about 50 µg Zn per g Hb, and total leukocyte zinc is normally about 100 ± 25 µg/10^{10} cells.

Fecal excretion includes both unabsorbed dietary zinc and zinc resecreted into the gut. The total amount normally equals the total dietary intake and is of the order of 10 to 15 mg/day in healthy populations. In contrast, urine output of zinc is normally only about 0.5 mg/day, but this can increase markedly during catabolic illness. The release of intracellular contents from skeletal muscle has been established as the source of the excess urinary zinc in the postoperative period, using zinc radiotracer labeling. Two patients took an oral dose of 5 µCi radioactive ^{65}Zn about a month before elective surgery for total hip replacement, allowing incorporation of the tracer into skeletal muscle. Urine output of radioactive zinc, total zinc, and total nitrogen was measured before operation and daily for 3 weeks after surgery. There was a large increase in the excretion of all of these, the peaks occurring at 10 days. There was a good correlation between radioactive zinc and total zinc in the urine of both patients, suggesting skeletal muscle as the source.[153] Urine zinc also increases more than threefold during short-term total starvation, as a result of release from skeletal muscle and excretion of ketone bodies.[146]

Functions

More than 300 zinc metalloenzymes occur in all six categories of enzyme systems. Important examples in human tissue include carbonic anhydrase, alkaline phosphatase, RNA and DNA polymerases, thymidine kinase carboxypeptidases, and alcohol dehydrogenase. The key roles of zinc in protein and nucleic acid synthesis explain the failure of growth and impaired wound healing observed in individuals with zinc deficiency. In some enzymes, such as Cu and Zn SOD, structural stability is ensured by zinc protein binding and the catalytic activity of the enzyme by the active copper site. Classifications of zinc enzymes, their structure and mode of action have been detailed in various texts.[106,180] Proteins can form domains able to bind tetrahedral zinc atoms by coordination with histidine and cysteine to form folded structures that have become known as "zinc fingers."[44] These biologically active molecules have important roles in gene expression by acting as DNA-binding transcription factors and play a key role in developmental biology and also

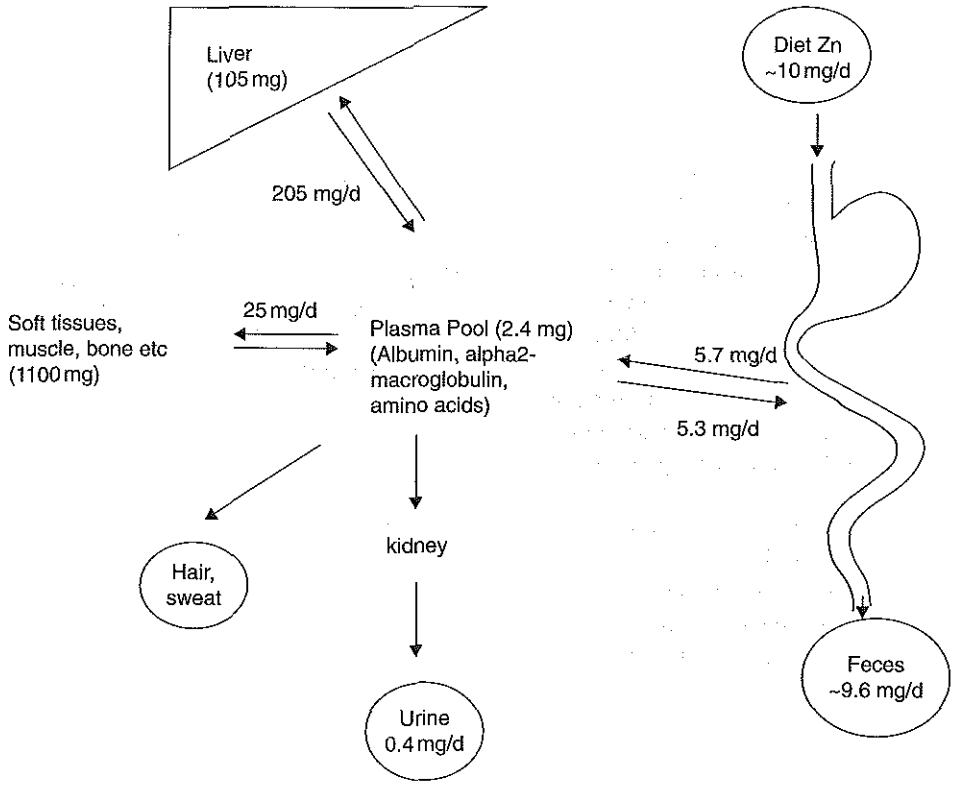


Figure 30-28 Summary of zinc metabolism.

in the regulation of steroid, thyroid, and other hormone synthesis.[150,586] Zinc binding to the metal response factor MTF1 activates metallothionein (Mt) expression. This multifunctional, low molecular weight protein (9000 to 10,000 Da) has a high content of cysteine and reversibly binds zinc. Mt is important in intracellular zinc trafficking and helps to maintain intracellular zinc concentrations. Hepatic synthesis of Mt is induced by interleukin-1, interleukin-6, and glucocorticoids in response to infection, trauma, and other stressors.[106,505]

Requirements and Reference Nutrient Intakes

In the United States, the Dietary Reference Intake (DRI) for zinc is 11 mg/day for men and 8 mg/day for women. Infants and young children need smaller amounts. Increased amounts are required during pregnancy and lactation. Strict vegetarians may need as much as 50% more zinc per day because of the increased phytic acid and fiber in their diet.[174]

Intravenous Supply

Stable adult patients require 2.5 to 4.0 mg/day (40 to 60 μmol/day), but in those who are depleted or who have increased gastrointestinal losses, the requirement is about 6 mg/day (100 μmol/day).

Clinical Deficiency

As might be expected from the multiple biochemical functions of zinc, the clinical presentation of deficiency disease is varied, nonspecific, and related to the degree and duration of the depletion.[226,305,446] Signs and symptoms include depressed growth with stunting; increased incidence of infection, possibly related to alterations in immune function; diarrhea; altered cognition; defects in carbohydrate use; reproductive teratogenesis; skin lesions; alopecia; eyesight defects; and other adverse clinical outcomes.

Effects on Growth. It has been claimed that dietary zinc deficiency is prevalent in countries worldwide where a cereal-based diet high in phytate and fiber but low in animal protein is common.[448] This could affect as many as 2 billion people and may be a major public health issue comparable with the recognized deficiencies of iron and iodine. In children, reduced growth and other developmental abnormalities are reversible by zinc supplementation. A meta-analysis of some 37 intervention trials shows that zinc supplementation has a significant effect upon linear growth and weight regain.[78] Studies have also shown that lean tissue retention and protein synthesis are increased if zinc is added to therapeutic regimens used in famine relief, especially when soya-based formulations with a high phytate content were being used as a protein source.[202]

It is known that the zinc in human breast milk is efficiently absorbed because of the presence of factors such as picolinate and citrate. However, the total quantity of zinc in breast milk is related to maternal nutritional status, and there is a physiological decline in the zinc content of "mature milk" after about 6 months lactation. Although cases of

symptomatic zinc deficiency have been reported in breast-fed infants,[241,267] the need for zinc supplementation for women in low-income countries during pregnancy is controversial. Reduction of neonatal morbidity and incidence of infections is reported in some studies, but the large-scale introduction of the zinc supplementation of pregnant women necessitates more controlled trials.[434]

Acrodermatitis Enteropathica. Acrodermatitis enteropathica (AE) is characterized by periorificial and acral dermatitis, alopecia, and diarrhea. Patients with this disorder have abnormally low blood zinc levels (<30 μg/dL); symptoms are reversed by oral zinc supplementation, with this being diagnostic.[31] This formerly fatal condition is an autosomal recessive inborn error affecting zinc absorption from the intestinal mucosa, but the location of the gene defect has not yet been identified.

Parenteral Nutrition. When clinical techniques were developed for TPN in the 1960s and 1970s, the early sources of amino acids were based on whole protein hydrolysates that had zinc and other trace elements present as contaminants. When these were replaced with mixtures of synthetic amino acids in the 1980s, this necessitated the addition of trace element additives. Some patients requiring intravenous feeding after surgery are likely to be significantly zinc depleted because of poor oral intake before and after surgery. They may also have increased zinc losses from the intestinal tract via diarrhea and in urine from catabolism of muscle during periods of negative nitrogen balance. Diarrhea, mental depression, dermatitis, delayed wound healing, and alopecia are seen during the anabolic period of weight regain when there is insufficient zinc in the nutritional regimen to support tissue repair.[300] Provision of adequate zinc intravenously to achieve a positive zinc balance is associated with improvement in nitrogen balance.[625] Routine provision of 100 μmol/day (6.5 mg) in the IVN regimen is normally adequate in stable patients,[527] but increased amounts of zinc and other micronutrients are required in the most severely injured patients.[526]

Infectious Disease. Zinc depletion impairs immunity[446] and has a direct effect on the gastrointestinal tract,[547] which increases the severity of enteric infections. A placebo-controlled trial of zinc supplementation (10 to 20 mg/day) of 1240 children ages 6 to 30 months was conducted in North India. There was a substantial reduction in the incidence of both severe and prolonged diarrhea in the treated group.[52] A review of controlled trials of zinc supplementation of children in low-income countries found significant clinical benefits.[57] Six out of nine trials in cases of persistent diarrhea claimed improvement; in five trials in respiratory disease, there was a lower rate of infection. Some caution is required with the doses of zinc employed. In a study of severely malnourished children, those treated with doses of 3 to 6 mg Zn per kg had a significantly increased mortality compared with those given 1.0 to 1.5 mg Zn per kg.[136] Interaction with vitamin A is important, since in populations at risk of zinc and vitamin A deficiency, provision of zinc alone increased the incidence of respiratory infection, but when vitamin A was also added, respiratory infections were decreased.[455]

Other Conditions. Other groups of individuals are considered to be at risk either from a marginal dietary deficiency or from an acquired deficiency secondary to disease. These groups would include female adolescents during pregnancy and lactation. Also affected may be patients with malabsorption syndrome, inflammatory bowel disease, alcoholic liver disease, and anorexia nervosa.[305] A significant proportion of cases of sickle cell anemia have clinical signs and symptoms and some laboratory abnormalities of zinc deficiency. These patients respond well to zinc supplementation.[447]

Subclinical Effects of Deficiency

When zinc deficiency is not severe enough to cause clinical signs and symptoms, it may still have a subclinical effect on immune function, the synthesis and action of hormones, and neurological function.

Immune Function. Patients with zinc deficiency in the Middle East were known to die before the age of 25 because of various infections and parasitic disease. In zinc deficiency, there is a reduction in the activity of serum thymulin, the thymus-specific hormone that is involved in T-cell function, and an imbalance develops between Th1 and Th2 helper cells. The lytic activity of natural killer cells also decreases. Moreover, zinc is also necessary for intracellular binding of tyrosine kinase to the T-cell receptors CD-4 and CD-8, which are required for T-lymphocyte activation. These complex changes result in an impairment of cell-mediated immunity and may be the basis for increased infection rates seen in marginal zinc depletion.[446]

There have been suggestions that zinc supplements may be beneficial in reducing the severity or duration of the common cold. Studies have been inconsistent, putative benefits small, and given the doses of zinc used, a high incidence of side effects was encountered.[362]

Hormones. Zinc is thought to have a role in the synthesis and actions of many hormones, via zinc transcription factors. Zinc depletion is associated with low circulating concentrations of testosterone, free T_4, insulin-like growth factor (IGF)-1, and thymulin.[446] Both plasma IGF-1 and growth velocity increase in zinc-supplemented children.[421]

Neurological Effects. Severe zinc deficiency is known to affect mental well-being, with varying degrees of confusion and depression being consistent with zinc enzymes having important activity in brain development and function. The history of zinc in relation to the brain and possible relevance to human disease has been reviewed.[122,493]

Toxicity

Clinical effects of ingestion of a zinc-contaminated diet are abdominal pain, diarrhea, nausea, and vomiting (see Chapter 35). Single doses of 225 to 450 mg of Zn can induce vomiting, with milder forms of gastrointestinal upset being

reported at 50 to 150 mg Zn/day, (dosages that were initially used in therapy). More than 60 mg Zn per day can result in copper depletion by causing intestinal blockade of intestinal absorption. The U.S. Nutrition Board has set the tolerable upper level of intake for adults at 40 mg/day.[174]

Laboratory Assessment of Status

Although plasma zinc determination is insensitive to dietary zinc intake and subject to a variety of influences, it remains the most widely used laboratory test to confirm severe deficiency and to monitor adequacy of zinc provision, especially if interpreted together with changes in serum albumin and the APR. No feasible laboratory procedures are established for clearly identifying populations with marginal zinc depletion. The clinical and biochemical responses to zinc supplementation are therefore used to postulate a marginally zinc-depleted state.

Plasma Zinc. Plasma samples are preferred to serum for zinc analysis because of possible zinc contamination from erythrocytes, platelets. and leukocytes during clotting and centrifugation. Plasma zinc levels are most commonly measured by FAAS, although photometric methods are available.

A study using stable zinc isotope tracers during experimental induction of acute zinc depletion (0.23 mg Zn per day) found that the plasma zinc level took 5 weeks to decline to 65% of the baseline values, and that the observed fall was caused by a reduction in zinc release from the most slowly turning over zinc pool.[306] Care has to be taken in controlling numerous preanalytical factors that will lower plasma zinc independently of dietary intake. These include collection of sample in relation to meals, time of day, and use of steroid-based medications, such as the contraceptive pill. Any cause of hypoalbuminemia will also lower plasma zinc. Plasma albumin is a negative acute phase reactant and is redistributed into interstitial spaces from the plasma pool during infection, after trauma, and in chronic disease. The induction of hepatic Mt synthesis during the APR, and subsequent sequestering of zinc, further lowers the plasma level.[523] It is therefore essential to consider plasma zinc results along with plasma albumin and plasma CRP or another marker of the APR.

Blood Cell Zinc. Some investigators have suggested that the zinc content of white cells and platelets better reflects tissue zinc.[571,610] The zinc content of neutrophils, lymphocytes, and platelets has been shown to decline more rapidly than plasma zinc in experimental studies of zinc depletion in humans.[446] However, the relatively large volume of blood required and problems with contamination make large-scale application to patients in the hospital or to population surveys difficult, especially in studies involving children.

Zinc in Hair. Low hair zinc has been associated with poor growth in children, and has been used as a criterion for initiating supplementation studies.[174] However, variables such as hair growth rate and external contamination from hair dyes and cosmetics can cause inconsistent results. Results from individual patients are difficult to interpret.

Zinc-Dependent Enzymes. Despite the large number of zinc metalloenzymes that have been identified, no single enzyme assay has yet found acceptance as an indicator of zinc status. This may be due to avid retention of zinc by these enzymes, even in the face of dietary zinc depletion, and to difficulties with reproducible measurements of activity. However, bone-specific alkaline phosphatase, extracellular SOD, lymphocytes, and plasma 5-nucleotidase appear to be responsive to zinc intake.[626]

Metallothionein. The determination of Mt in red cells and MT mRNA in circulating monocytes is considered of probable value since Mt falls in zinc deficiency. However, the clinical use of these measurements is not yet confirmed by large-scale investigations of depleted populations.[626]

Urine Zinc. There is a slight fall in the urinary excretion of zinc during dietary deficiency. Difficulties of sample contamination during collection make this of limited practical value. Increases in urine zinc are, however, an important source of loss in the severely injured catabolic patient, although measurement is rarely required except in research studies.

Reference Intervals

Serum zinc concentrations are generally 5% to 15% higher than plasma because of osmotic fluid shifts from the blood cells when various anticoagulants are used. Plasma zinc concentrations exhibit both circadian and postprandial fluctuations. Concentrations decrease after food and are higher in the morning than in the evening.

A reference interval, for clinical guidance, is 80 to 120 µg/dL (12 to 18 µmol/L).

Fasting morning values of plasma zinc below 70 µg/dL (10.7 µmol/L) on more than one occasion require further investigation. Results below 30 µg/dL (5 µmol/L) suggest likely deficiency. Urine zinc excretion lies in the range from 0.2 to 1.3 mg/24 hr (3 to 21 µmol/24 hr).

Other Possibly Essential Elements

More than 15 additional trace elements are considered by some investigators to have a potentially important role in human medicine. A review by Nielsen considers these in detail and discusses emerging concepts of "essentiality."[419] For some such as lead, cadmium, arsenic, aluminum, and nickel, the clinical laboratory will primarily consider them as toxic elements (see Chapter 35). Others, such as lithium and fluoride, are classified as pharmacologically beneficial and monitoring of dosage may be required. Some elements can be considered "nutritionally beneficial" and are reported to produce "restorative health effects" at lower dosages. Evidence comes mainly from animal studies when dietary depletion of the element is combined with other metabolic, hormonal, or physiological "stressors."

For a few elements (boron, silicon, and vanadium), the circumstantial evidence is considered to be strong, although no agreed biochemical mechanism is established. For this

reason the DRI report,[174] which considered in detail the nutritional aspects of arsenic, boron, nickel, silicon, and vanadium, was unable to establish dietary recommendations. For boron, silicon, and vanadium, it was noted that measurable responses in humans have been observed during variations in the dietary intake of these elements. There is promotion of these and other elements by the supplement industry and the clinical chemist may be asked for advice and possibly for monitoring of dosage in cases of suspected toxicity. AAS, ICP-OES, and ICP-MS methods can be applied to the determination of most of these elements in biological samples.[390]

The contamination of TPN solutions by small amounts of metals, such as Al, Pb, Cd and Ni, could also be a problem, as could the lack of others, such as Si, B, and V, when very long-term nutritional support is required.

Fluoride

Fluoride (Fl) is the most widely used of the "pharmacologically beneficial trace elements" in the area of public health. Dental caries has been described as the last major epidemic of preventable bacterial disease and dental decay leads to tooth loss, nutritional problems, and systemic infections.[97]

Dietary Sources

Many studies over the last 50 years have established that addition of fluoride to drinking water reduces the incidence of tooth decay, and more than 60% of the U.S. population now uses fluoridated water. Clinical studies from 1950 to 1980 in 20 different countries found that adding fluoride to community water supplies, within the interval 0.7 mg to 1.2 mg/L, reduced the incidence of caries by 40% to 50% in primary (infant) teeth and by 50% to 60% in permanent teeth.[129] The subject is controversial and there is opposition to "mass medication" with fluoride. Reviews of the benefits and the risks associated with the use of fluoride are available.[97-99,247,400]

Fluoride supplementation of salt, sugar, and milk has also been used in areas where fluoride is not added to water supplies.

Function

The fluoride ion can exchange for hydroxyl in the crystal structure of apatite, a main component of skeletal bone and teeth. This stabilizes the regenerating tooth surface. Fluoride is available from saliva and may also be released from dental plaque at low pH.[98] Initially, benefit was considered solely to be for the erupting teeth of children, but topical effects on adult teeth are now also thought to reduce decay. There is some initial evidence from small studies that pharmacological doses of fluoride may reduce the incidence of bone fracture in patients with osteoporosis. However, a metaanalysis of fluoride therapy from 11 controlled studies on 1429 subjects found that although this increased lumbar bone density, the incidence of vertebral fractures was not significantly decreased.[247]

Absorption, Transport, Metabolism, and Excretion[99]

Fluoride ions are absorbed from both the stomach and the small intestine. The soluble salts are efficiently absorbed, and the peak increase of fluoride in blood plasma is within 1 hour of ingestion. Ions are rapidly cleared from plasma into tissue in exchange with anions, such as hydroxyl, citrate, and carbonate. At least 95% of the 2.6 g of total body fluoride is located in bones and teeth. Almost 90% of excess fluoride is excreted in urine.

Toxicity

Dental fluorosis is the mottling of enamel in the erupting teeth of children and it is now estimated to affect around 20% of the population. This can be a disfiguring condition and occurs in a higher proportion of children than initially expected.[612] This is possibly due to the ingestion of fluoride-containing toothpaste by children. It is suggested that "pediatric" toothpastes with lower fluoride content be made available in areas where there is existing fluoridation of the water supply.[98]

Occupational exposure to inhaled fluoride dusts in cryolite workers during aluminum refining has resulted in severe bone abnormalities, but safety equipment now limits such exposure. No cases of skeletal fluorosis are attributed to use of controlled fluoridation of water supplies.[99] However, skeletal fluorosis may occur in areas of the world where naturally occurring drinking water has high levels of fluoride, such as China and the Indian subcontinent. It is thought that exposure to fluoride intakes of 10 to 25 mg/day for 10 years or more may result in skeletal fluorosis, but other nutritional factors may make these populations more susceptible.[247]

A number of diverse adverse effects have been attributed to water fluoridation. Investigators have found no convincing evidence of increased rates of cancer, heart disease, kidney disease, liver disease, presenile dementia, birth defects, or Down syndrome.[247]

Laboratory Assessment of Status

Laboratory analysis of drinking water may be required to assess possible fluoride excess in natural well waters and may also be necessary during incidents of failure of the equipment used to treat drinking water. The determination of fluoride in urine can be used to assess exposure to different sources of fluoride.[303] For drinking water and urine, direct determination using a fluoride-specific electrode is employed. For food, feces, and tissue, prior separation of fluoride from the sample matrix is required using a Conway diffusion procedure.[99] The combination of the fluoride-electrode with flow injection has allowed a rapid and sensitive method to be used for serum and urine fluoride analysis.[269]

Reference Intervals

Concentrations of fluoride in body fluids and tissue will vary widely depending upon the fluoride content of drinking water and input from diet, toothpaste, and mouth rinses. For

urine, a guideline interval is 0.2 mg to 3.2 mg/L (10.5 to 168 μmol/L).

Boron

Boron (B) may be the next element to be recognized as essential in human nutrition. The evidence is largely circumstantial because there is no clear biological function for boron in humans.

Function

Responses to dietary deprivation of boron have been described with alterations in calcium metabolism, brain function, and energy production.[419] The responses from a low dietary boron intake (0.25 mg/2000 kcal) for 63 days and the effects of supplementation with 3.0 mg/day included increases in 25-hydroxycholecalciferol, decreases in calcitonin, decreased serum glucose, and increased serum triglycerides among other biochemical changes.[419] Some of the effects were more evident when dietary copper was marginal and magnesium inadequate. There is a necessity for further research to clarify the role of boron in human and animal physiology and to establish a dietary requirement.[133]

Dietary Sources

It is thought that the acceptable safe range of boron intake is from 1 to 13 mg/day, and there is evidence that some people are consuming less than 1 mg/day. Plant foods, especially fruits, leafy vegetables, nuts, and legumes, are good sources, whereas meat, fish, and dairy products are not.[419]

Absorption, Transport, Metabolism, and Excretion

More than 90% of dietary boron is absorbed as boric acid, $B(OH)_3$, and transported in blood in this neutral form, which may be readily excreted in urine.

Laboratory Assessment of Status

Problems with contamination and losses of volatile boron compounds during sample preparation have limited the reliable documentation of boron concentrations in human tissue and body fluids.[138] A complex technique involving a porous graphite column—inductively coupled plasma-atomic emission spectrophotometry (ICP-AES)—and an ICP time of flight mass spectrometer (TOF-MS) has been developed for investigations of boron neutron capture in cancer therapy.[552] Adaptation of this method to nutritional studies of boron should be possible.

CHAPTER 31

Hemoglobin, Iron, and Bilirubin*

Trefor Higgins, M.Sc., Ernest Beutler, M.D., and Basil T. Doumas, Ph.D.

Hemoglobin (Hb), iron, and bilirubin are analytes that collectively may be viewed in terms of a manufacturing process in which the raw material (iron) is incorporated with other raw materials in a multistage complex process leading to a finished product (Hb). This finished product has a limited lifespan after which degradation into the waste product (bilirubin) occurs. Within this process many exquisite biochemical control, conservation, and synthesis mechanisms are found. This process may be disrupted by a deficiency in the supply of raw material, lack of control or synthesis mechanisms, excessive loss of finished product, or excessive conversion to or deficiency in the elimination of waste products. These disruptions are manifest in the clinical disorders of iron deficiency anemias, liver disease, and various genetic diseases—including Crigler-Najjar and Gilbert syndromes, hemoglobinopathies, and thalassemias.

Reliable analytical methods for the measurement of these analytes were among the first to be developed for routine use in the clinical laboratory. Laboratory analysis has contributed significantly to our understanding of the physiological role of these analytes and continues to be crucial in the diagnosis of diseases associated with disruptions in supply, synthesis, and elimination of these parameters.

HEMOGLOBIN

Hb is a hemoprotein whose primary function is to transport oxygen from the lungs to the body tissue. It was first isolated in 1849 and was the first oligomeric protein to be characterized by ultracentrifugation and to have its (1) molecular mass accurately determined; (2) physiological function described; and (3) following the 25-year study of Max Perutz and colleagues in Cambridge, its structure defined by x-ray crystallography.[138] In 1949 Linus Pauling and H. Itano[135] showed that the Hb from patients with sickle cell disease differed from normal Hb by having two to four more net positive charges. From 1956 to 1959 Vernon Ingram published a series of four papers that identified the reasons for the charge difference by locating the single amino acid difference between Hb from normal individuals and those with sickle cell disease and so described the first hemoglobinopathy.[85-88]

Thalassemias and hemoglobinopathies are clinical disorders related to Hb pathophysiology. Regarding the former, inadequate production of α- or β-globin chains results in α- or β-thalassemia, respectively. Modifications in the amino acid sequence of either the α- or β-chains results in hemoglobinopathies.

BIOCHEMISTRY

Hemoglobin is a globular protein with a diameter of 6.4 nm and a molecular weight of approximately 64,500 Da. As shown in Figure 31-1, Hb consists of four globin subunits arranged to resemble a thick-walled shell with a small central cavity. Each globin chain is looped about itself to form a pocket or cleft in which the heme group nestles. Normally, this heme pocket is formed entirely by nonpolar (hydrophobic) amino acids. The heme moiety is suspended within this pocket by an attachment of its iron atom to the imidazole group of the proximal histidine (position 92 of the β-chain [β92] or position 87 of the α-chain [α87]). The imidazole group of the distal histidine (β63 or α58) is also in contigu-

*The authors gratefully acknowledge the original contributions of Virgil F. Fairbanks and George G. Klee (hemoglobin and iron) and Keith G. Tolman and Robert Rej (bilirubin) upon which portions of this chapter are based.

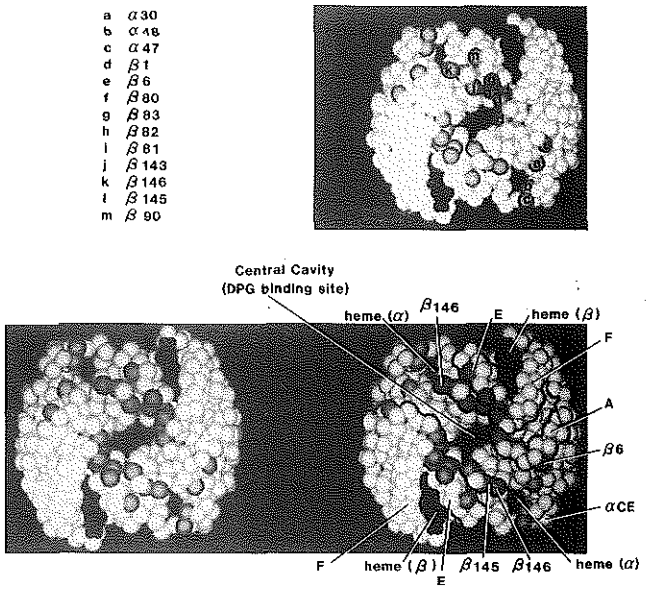

Figure 31-1 Model of the Hb tetramer with the β-chain subunits facing the reader. Amino acids are represented as spherules. Those that are shaded affect Hb mobility in citrate agar gel. Spherules labeled *d, j, k,* and *l* in the upper panel constitute the 2,3-diphosphoglycerate binding site and are important in regulation of the oxygen affinity of Hb. The lower panel is a stereo pair for three-dimensional viewing. To obtain the three-dimensional effect, hold the illustration at arm's length. The β-globin chains appear to be between the reader and the more distant α-chains. On the right, some of the segments of the β-globin chain have been outlined, and segments and critical components have been marked. β146 is the COO^- end of the β-chain; β6 is the site of amino acid substitutions responsible for Hbs S and C. *(From Winter WP, Yodh J. Interaction of human hemoglobin and its variants with agar. Science 1983;221:175-8. Copyright 1983 by the American Association for the Advancement of Science.)*

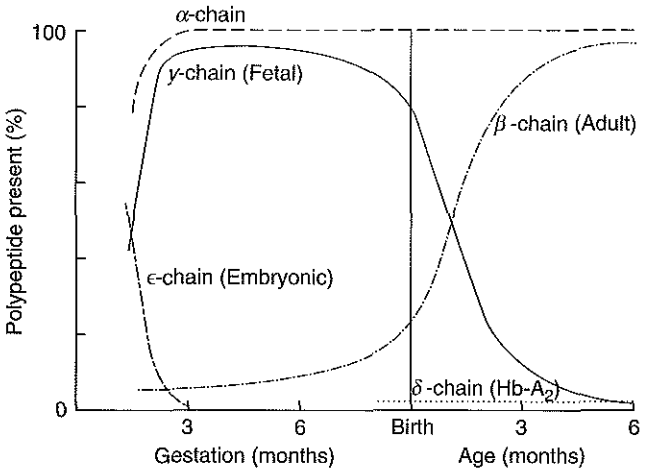

Figure 31-2 Changes in relative proportions of globin chains at various stages of embryonic, fetal, and postnatal life. *(Reprinted from Huehns ER, Dance N, Beaven GH, Hecht F, Motulsky AG. Human embryonic hemoglobins. Cold Spring Harbor Symp Quant Biol 1965;29:327-331.)*

ity with the iron of heme, but it appears to swing in and out of this position to permit the passage of O_2 into and out of the Hb molecule. The four iron atoms are in the divalent state, whether Hb is oxygenated or deoxygenated.

Globin Structure of Normal and Fetal Hemoglobin

In normal human adults, Hb A is composed of two normal α- and two normal β-polypeptide chains and is represented symbolically as $\alpha_2\beta_2$; it represents at least 96% of the total Hb contained in a sample of whole blood. Hb A_2 is typically about 2.5% to 3.0% of total Hb; it contains two α- and two δ-chains and is designated as $\alpha_2\delta_2$. *Fetal Hb (Hb F)* predominates during fetal life but rapidly diminishes during the first year of postnatal life. In normal adults, less than 1% of Hb is Hb F. It consists of two α- and two γ-chains ($\alpha_2\gamma_2$).

In early embryonic life, the yolk sac produces the globin chains zeta (ζ) and epsilon (ε). These globin chains combine to form the major embryonic hemoglobins Hb Gower 1($\zeta_2\varepsilon_2$) and 2($\alpha_2\varepsilon_2$) and Hb Portland 1($\zeta_2\gamma_2$) and 2($\zeta_2\beta_2$). Production of the ζ-chain ceases at a gestational age of approximately 4 months (Figure 31-2). Production of α- and γ-chains start at about 6 weeks gestation, with Hb F (fetal hemoglobin, $\alpha_2\gamma_2$) increasing in concentration to become the major Hb found in the fetus. Glycine or alanine may be found at position 136 of the γ-chain in the fetus, giving rise to two distinct γ-chains designated $^G\gamma$ and $^A\gamma$, respectively. Formation of Hb A ($\alpha_2\beta_2$) commences at about 28 weeks gestation and at birth can form up to 15% of the total Hb, with the remainder of the Hb consisting mainly of Hb F with a very small amount of Hb A_2. The production of the γ-chain declines after birth, and normal adult Hb F values are usually obtained by 1 year of age but may be elevated until 2 years of age.

Protein Structure

As with all proteins, the function of Hb is dictated by its primary, secondary, tertiary, and quaternary structure.

Primary Structure. The α- and non–α-globin chains of Hb are 141 and 146 amino acid residues in length, respectively. There is some sequence homology, with 64 individual amino acid residues in identical positions in both α- and β-chains. The β-chain differs from the δ- and γ-chains by 39 and 10 residues, respectively. The amino terminal of the β-globin chain is the site of attachment of glucose (Hb A_{1c}), urea, and salicylate.[30] The carboxy terminal amino acid of the β-chain is tyrosine and can function as a part of salt bridges. Although there are no disulfide bonds, there are six –SH groups (from cysteine at positions α104, β93, and 112). The γ-chain has a glycine amino terminal and the alkali resistance of Hb F is attributed to the presence of threonine and tryptophan at positions 112 and 130 of the γ-chain, respectively. The γ-chain is unique in that it is the only globin chain to be susceptible to acetylation and acetylated Hb F is a prominent feature in cord and neonatal blood and may form as much as 25% of the total Hb.

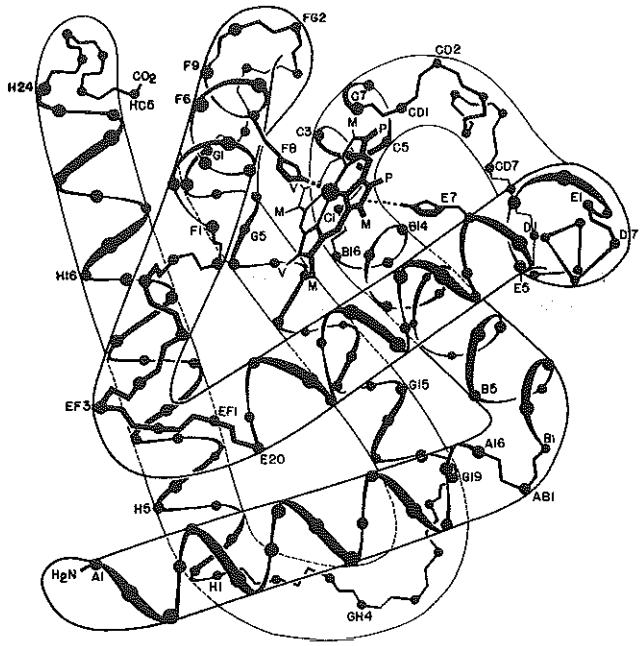

Figure 31-3 Structure of the Hb subunit. Chains of amino acids in spiral or helical segments are linked by short, nonhelical segments. The helical segments are designated A through H. In this illustration, amino acids are designated in accordance with the helical or nonhelical segment in which they occur. *(From Dickerson RE. X-ray analysis and protein structure. In: Neurath H, Ed. The Proteins: composition, structure and function. 2nd ed. Vol. 2. New York: Academic Press, 1964:603-778.)*

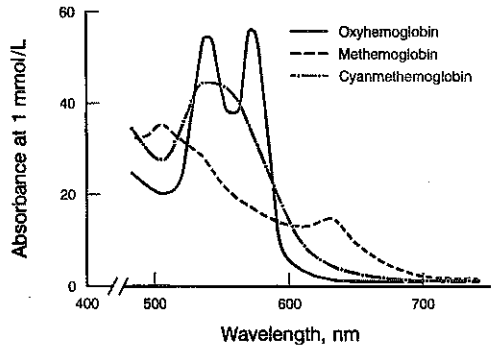

Figure 31-4 Spectrophotometric absorption curves for oxyhemoglobin, methemoglobin, and cyanmethemoglobin (authors' data). Oxyhemoglobin and cyanmethemoglobin are used in measuring the Hb concentration. The peak at 630 nm, which is distinctive for methemoglobin, is abolished by addition of cyanide, and the resultant decrease in absorbance is directly proportional to the methemoglobin concentration. All heme proteins exhibit their maximum absorbance in the Soret band region of 400 to 440 nm. Because the absorbance of Hb in the Soret region is approximately 10 times the absorbance at 540 nm, the Soret peaks have been omitted from this diagram. The absorbance curve for methemoglobin is greatly influenced by small changes in pH. The curve given here was obtained at a pH of 6.6.

Secondary Structure. Approximately 75% to 80% of the polypeptide chains of the α- and non–α-chains are arranged in helices, with the remainder forming non-helical turns. The β-chain of Hb A is arranged into eight helices identified as A through H (Figure 31-3). In contrast, the α-chain is missing an equivalent of the D helix and so has only seven helices. Nomenclature within the helices identifies the helix and position within the helix of the amino acid residue (e.g., F3 is the third amino residue in the F helix). Amino acid residues in the peptide chains that join adjacent helices are described by the identification of the two adjacent helices and position of the residues within the joining peptide. For example, EF3 would be the third residue in the peptide joining the E and F helices.

Tertiary Structure. The tertiary structure of Hb refers to the arrangement of the helices into a three-dimensional, pretzel-like structure. The heme group, located in a crevice between the E and F helices, is attached to histidine residues in each globin chain. This attachment is essential to maintaining the secondary and tertiary structure of the globin chains.

Quaternary Structure. The quaternary structure of Hb results from the attachment of the four globin chains to each other. Strong $\alpha_1\beta_1$ and $\alpha_2\beta_2$ dimeric bonds hold the molecule in a stable form. The tetrameric $\alpha_1\beta_2$ and $\alpha_2\beta_1$ bonds make significant contributions to the stability of the structure. The shifting, rotation, and sliding in the quaternary structure result in a number of physiological effects, including the sigmoid oxygen dissociation curve and the Bohr effect.

Modified Hemoglobins

In addition to the Hbs discussed above, carboxyhemoglobin, methemoglobin, and sulfhemoglobin are other Hbs whose structure has been environmentally or chemically modified.

Each of the modified Hbs has a characteristic spectral pattern as shown in Figure 31-4. These spectral characteristics form the basis of analysis in the many co-oximeters and blood gas analyzers that provide, in a single analysis, the simultaneous quantitative measurement of carboxyhemoglobin, methemoglobin, and sulfhemoglobin. The spectral scans are performed using multidiode arrays covering a wide range of wavelengths followed by patented calculations that discriminate between the normal and modified Hbs.

Carboxyhemoglobin

Carboxyhemoglobin is formed by the preferential attachment of carbon monoxide over oxygen to Hb. Carboxyhemoglobin concentrations (usually expressed as a carboxyhemoglobin saturation) have been known to reach 20% in individuals who are exposed to significant workplace concentrations of carbon monoxide. For example, police directing traffic at busy intersections and workers in radiator and welding shops have high carboxyhemoglobin concentrations at the end of the working day. The ability to perform heavy manual work or complex tasks is impaired at

carboxyhemoglobin concentrations of 10% or less.[31] Faulty home furnaces and automobile exhaust systems can produce large amounts of carbon monoxide, sometimes with tragic results. Carboxyhemoglobin saturation levels in the range of 15% to 25% may be associated with dizziness, headaches, and nausea, and greater than 50% saturation is considered life threatening.[162] Following removal of the exposed individual from the carbon monoxide source, there is a slow decline in carboxyhemoglobin concentration in keeping with the half-life of 4 to 5 hours at sea level.[163]

Methemoglobin

The iron of heme is normally in the reduced ferrous state (Fe^{2+}). Under alkaline conditions, the iron is oxidized to the ferric state (Fe^{3+}) by toxic agents, such as nitrates (found in some well waters), aniline dyes, chlorates, drugs—such as quinones, phenacetin, sulfonamides—or local anesthetics, such as procaine, benzocaine, and lidocaine. This oxidation converts the heme to hematin[183] and the Hb to methemoglobin. Patients with methemoglobin are cyanotic, since methemoglobin is unable to reversibly bind oxygen. Methemoglobin is normally reduced to Hb in the cell by the reduced form of nicotinamide-adenine dinucleotide (NADH)-cytochrome reductase system.

Hereditary methemoglobinemia is a rare condition first described in Europeans but later found in individuals of many racial backgrounds. Familial methemoglobinemia in an autosomal recessive mode of transmission is due to a deficiency in the enzyme NADH-cytochrome b5 reductase. Hb variants that stabilize the ferric iron state are associated with an autosomal dominant familial methemoglobinemia. Methemoglobinemia is treated by the administration of ascorbic acid or methylene blue.

Sulfhemoglobin

Sulfhemoglobin is produced by the reaction of sulfur-containing compounds with heme to form an irreversible chemical alteration and oxidation of Hb by the introduction of sulfur in one or more of the porphyrin rings. The most common cause of sulfhemoglobinemia is exposure to drugs[27]—such as phenacetin and sulfonamides with H_2S, the foul smelling component of sour gas—as a secondary cause. Sulfhemoglobin cannot transport oxygen, and cyanosis is noted at low concentrations.

Biosynthesis

The biosynthesis of Hb requires the biosynthesis of both heme and the globin polypeptide chains.

Heme Biosynthesis

Heme, ferrous protoporphyrin IX, consists of four pyrrole rings surrounding an iron atom with four of the six electron pairs of iron attached to the nitrogen atoms in the pyrrole rings (see Chapter 32). One of the remaining electron pairs attaches to a histidine residue in a globin chain, and the other pair is available for binding and transporting an oxygen molecule. The latter electron pair is protected from oxidation by the surrounding nonpolar amino acid residues of the globin chain. Hemin results from the relatively easy oxidation of the iron of heme from the ferrous to the ferric state.[183] To remain electrically neutral, a halide molecule, usually chloride, becomes attached to hemin. In alkaline solution hematin is formed by the replacement of the halide atom of hemin by a hydroxyl group.

The biosynthesis of heme, shown schematically in Figure 31-5, takes place primarily in the bone marrow and the liver and is an eight-step process[141] with each step involving a different genetically controlled enzyme. Details of this process are given in Chapter 32.

Heme synthesis is controlled by a regulatory negative feedback loop in which heme inhibits the activity of ferrochelatase and acquisition of iron from the transport protein transferrin. The decrease in iron acquisition leads to a decrease in iron uptake into the cell with subsequent decrease in δ-aminolevulinic acid and heme production. Iron deficiency and increased erythropoietin synthesis lead to the combination of the iron regulatory proteins with the iron-responsive elements in the transferrin receptor protein messenger ribonucleic acid (mRNA). This combination in turn leads to protection of the mRNA from degradation with subsequent increased uptake of iron into erythroid cells because of the increased expression of transferrin receptors on the cell membrane.

Globin Synthesis

The genes that control the α-like and ζ-globin chains are located in a cluster on chromosome 16 at position 16p13.3, which is near to the chromosome 16 telomere (Figure 31-6). The α-like gene extends over 28 kb and contains, reading from the upstream (5′) end to the downstream (3′) end of the DNA segment, an embryonic α-like ζ-globin gene, a hypervariable region (HVR), a pseudo–ζ-gene, a pair of pseudo–α-genes, a pair of functional α-globin genes, an unexpressed α-like θ gene, and finally another hypervariable region. Alpha-thalassemia arises from the deletion of one or more α-globin genes. Deletion of all four genes and subsequent production of Hb Bart's is incompatible with life.

The β-, γ-, and δ-globin genes are clustered closely together on chromosome 11 (Figure 31-6). Reading from the 5′ end, the gene sequence is an ε-gene followed by a two γ-genes (designated Gγ and Aγ, respectively), a pseudo–ψβ-gene, a δ-gene, and another β-gene. Therefore two genes determine the γ-chain, with one gene each determining the δ- and β-chains. There is substantial variability between individuals and groups in the α- and β-genes, with the most frequent being multiples of the ζ-, ψζ-, and α-genes.

In common with all genes, the globin genes consist of exons (coding sequences) and introns (intervening noncoding sequences), with codons (triplets of nucleotides) coding for specific amino acids. The globin genes have three exons and two introns with a promoter region (specific for the globin chain) at the 5′ end of each gene. The transcription

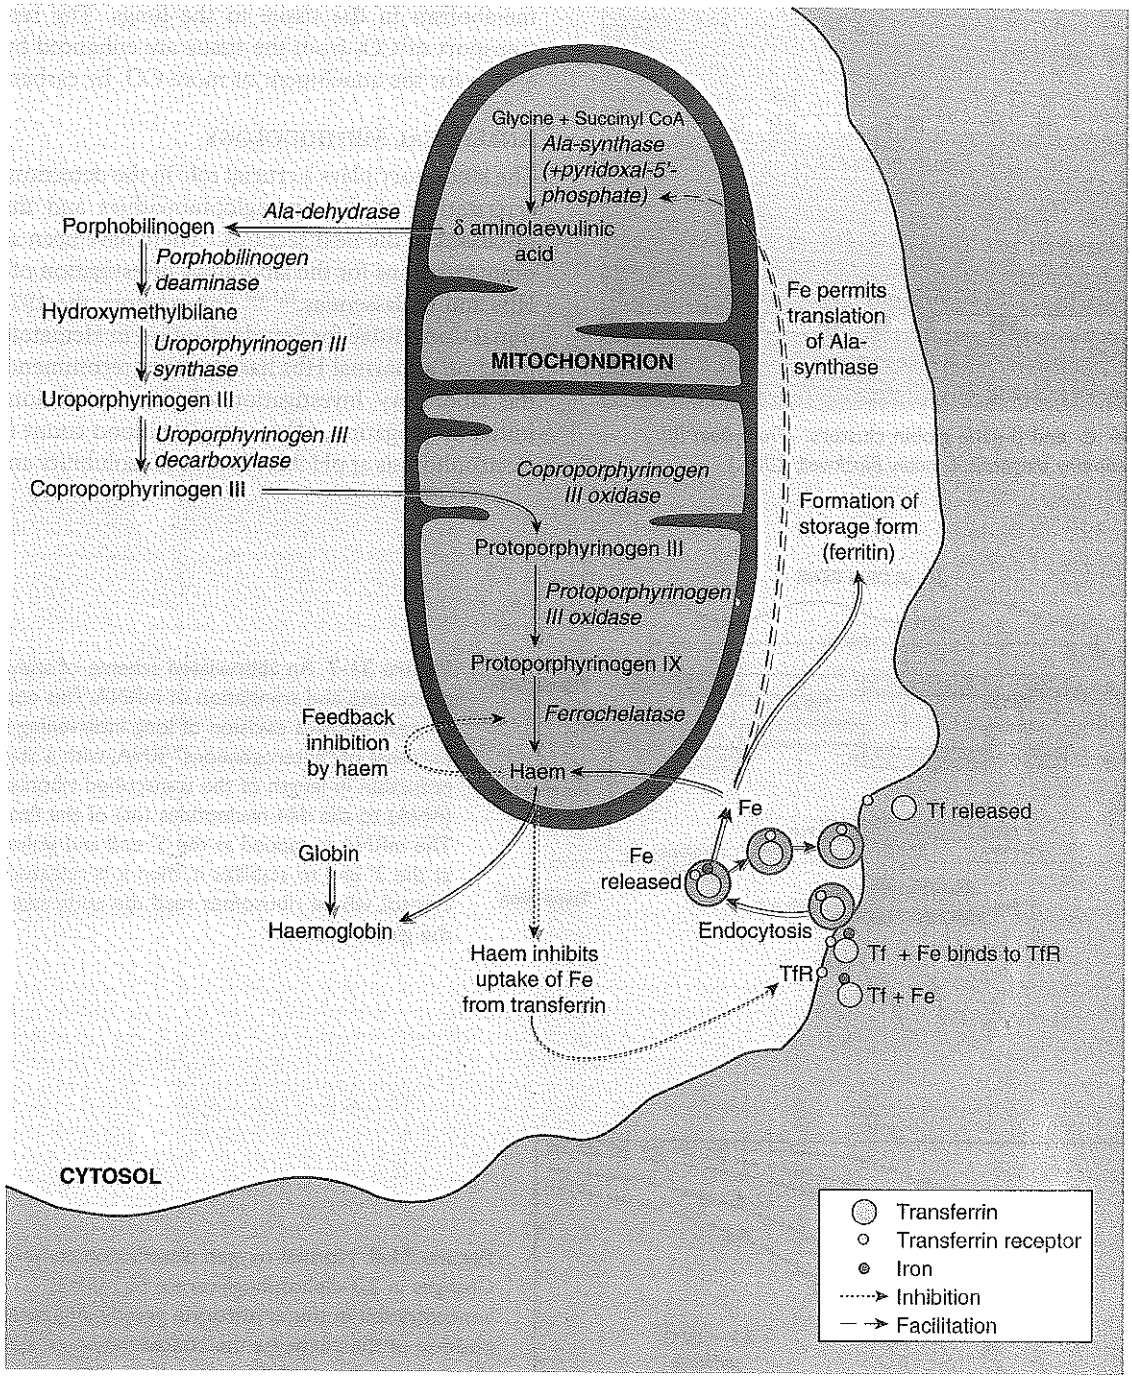

Figure 31-5 Heme synthesis. *(From Bain BJ: Haemoglobinopathy diagnosis. London: Blackwell, 2001.)*

and translation processes are the same as in any other synthesis of amino acid chains (Figure 31-7).

Physiological Role

The iron of heme is in the ferrous state and is able to combine reversibly with oxygen to act as the major oxygen-carrying moiety. The term cooperativity is used to describe the interaction of globin chains in such a way that oxygenation of one heme group enhances the probability of oxygenation of the other heme group. The Bohr effect refers to the reduction of oxygen affinity with a decrease in pH from the physiological range (7.35 to 7.45) to 6.0 and is another result of this cooperativity. As the pH of the tissue decreases as a result of the presence of the end products of anaerobic metabolism, CO_2 and carbonic acid, the delivery of oxygen to the exercising tissue is enhanced. The influence of pH on the oxygen dissociation of oxygen is shown in Figure 31-8. Carbon dioxide reversibly combines with the amino terminal groups of Hb to form carbamated Hb, facilitating the removal of about 10% of the CO_2 formed as a result of

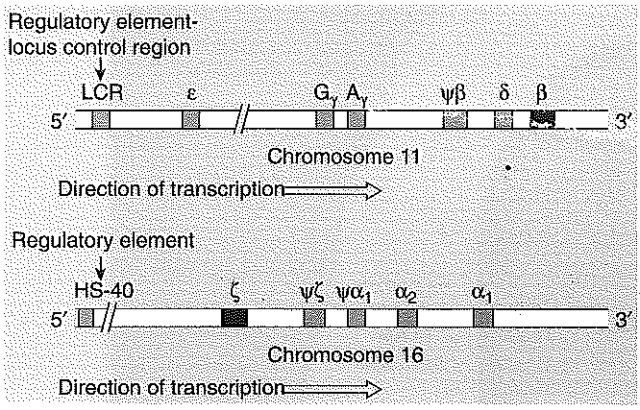

Figure 31-6 α- and β-gene globin clusters. *(From Bain BJ: Haemoglobinopathy diagnosis. London: Blackwell, 2001.)*

metabolism in the tissue to the lungs. The removal and transport of CO_2 from the tissue are enhanced by the preference for the attachment of more CO_2 by carbamated Hb.

Analytical Methodology

The laboratory plays a crucial role in the detection and characterization of the hemoglobinopathies and thalassemias discussed in the next sections.[4] There have been several recommendations for the laboratory investigation of abnormal Hbs and thalassemias.[29,73,89] For example, the 1978 International Committee for Standardization in Hematology expert panel on abnormal Hbs has prepared recommendations for the laboratory investigation of these conditions.[91] In its initial investigation, (1) a complete blood count (CBC), (2) electrophoresis at pH 9.2, (3) tests for solubility and sickling,

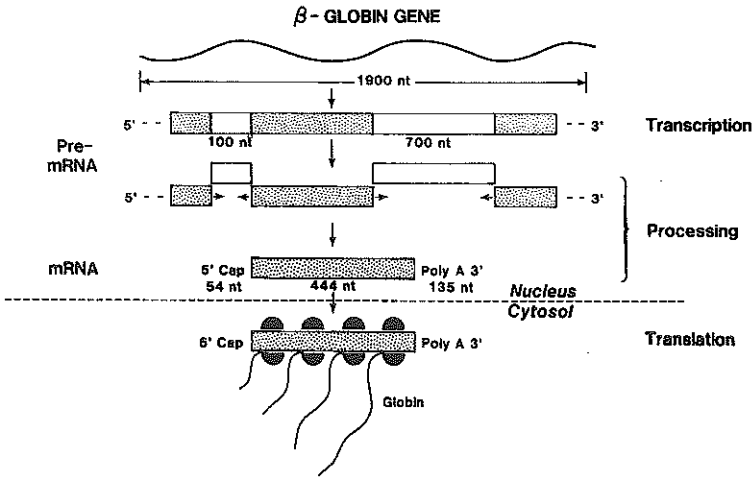

Figure 31-7 An abbreviated scheme of transcription, processing, and translation of mRNA. This complicated process involves excision of long intervening segments (introns) of "heterogeneous" RNA, with a stepwise reduction in length of the transcribed ribonucleic acid (RNA) to the 444 nucleotides (nt) of the final mRNA. The mRNA is capped at the 5′ end and polyadenylated at the 3′ end to stabilize it, then it is released into cytosol, where ribosomes read the code and assemble the globin chains.

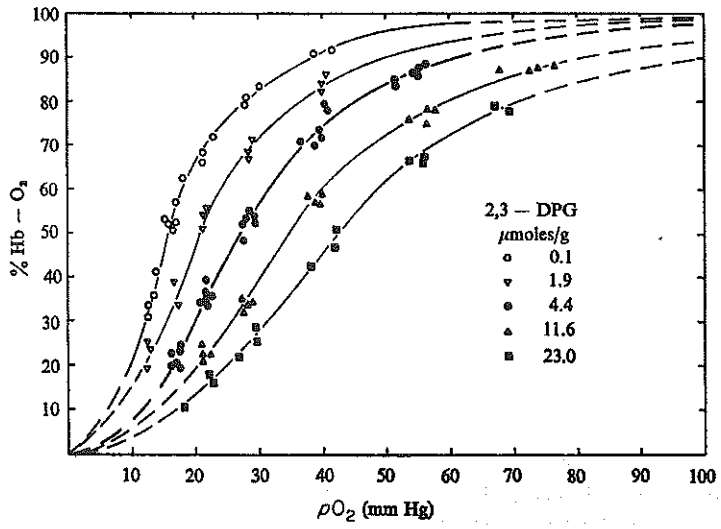

Figure 31-8 Normal oxygen dissociation curve of Hb. Changes in 2,3-diphosphoglycerate (2,3-DPG) concentration in the erythrocyte greatly influence the position of the curve. As the concentration of 2,3-DPG increases, the curve shifts to the right. *(From Duhm J. The effect of 2,3-DPG and other organic phosphates on the Donnan equilibrium and the oxygen affinity of human blood. In. Roth M, Astrup P. Eds. Oxygen affinity of hemoglobin and red cell acid base status [Alfred Benzon Symposium, IV], Copenhagen, Denmark: Alfred Benzon Foundation, 1972.)*

and (4) the quantification of Hb A_2 and Hb F were recommended. If an abnormal Hb was found as a result of these initial tests, further tests including electrophoresis at pH 6.2, globin chain separation, and isoelectric focusing were recommended by the panel. If the presence of an unstable Hb or Hb with altered oxygen affinity was suspected, then heat and isopropanol stability tests were recommended. Although new techniques have replaced some of these tests, the approach of using multiple assays in the initial investigation of hemoglobinopathies and thalassemias has shown merit and is used in many laboratories involved in the investigation of these disorders. In addition to the above tests, the iron status of the patient should be known either by measurement of ferritin or by iron/total iron binding capacity/saturation index. Information on the ethnicity and/or nationality of the patient, when allowed under patient confidentiality rules, may provide useful information since thalassemias (e.g., β-thalassemia in individuals of Mediterranean origin) and certain hemoglobinopathies (e.g., Hb S trait and homozygous S in African-Americans) are associated with certain ethnic and/or national groups.

Red blood cells (RBCs) and their indices, Hb, and related compounds are measured by several different types of analytical techniques and methods.

Preferred Specimen

The preferred blood sample is one collected with either K or Na salts of ethylenediaminetetraacetic acid (EDTA) as the anticoagulant. To minimize the formation of degradation products, which are especially noticeable as small bands eluting with similar retention time as Hb A_{1c} and Hb F on high-performance liquid chromatography (HPLC) analysis, testing should be performed within 5 days of collection and samples should be stored at 4 °C.

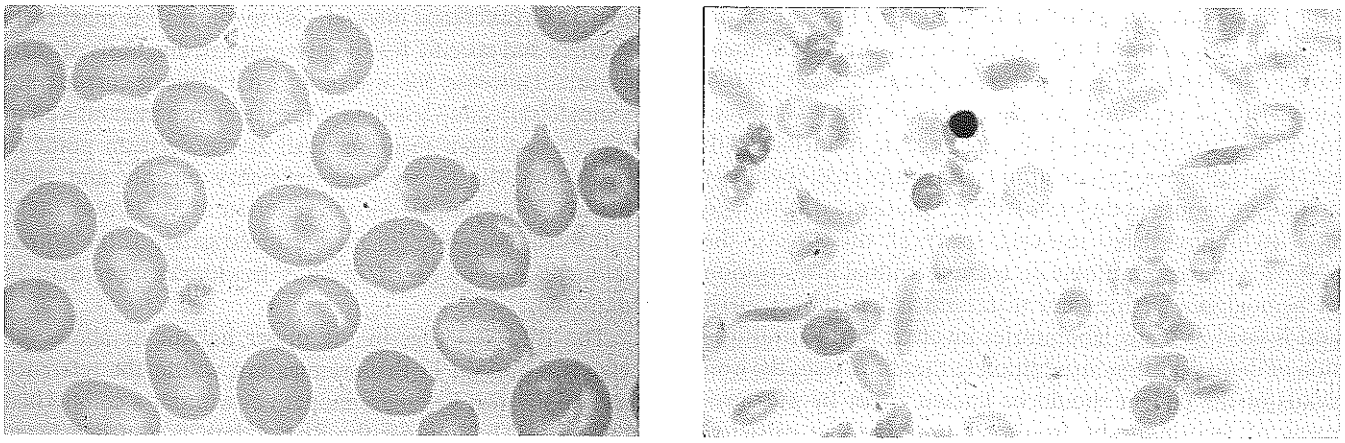
Analytical Techniques

Analytical techniques used to measure RBCs and their indices, Hb, and related compounds include determining a CBC, electrophoresis, immunoassay, molecular techniques, and sensitive separation techniques, such as HPLC, capillary electrophoresis, mass spectrometry, and deoxyribonucleic acid (DNA) analysis.

Complete Blood Count

The complete blood count (CBC) (1) counts RBCs, white blood cells, and platelets; (2) measures Hb; (3) estimates the red cells' volume, and (4) sorts the white blood cells into subtypes. Knowledge of red cell indices and the appearance of the peripheral blood film are vital to the diagnosis of both α- and β-thalassemias. Hemoglobinopathies have a lesser impact on the red cell indices but may present abnormal red cell morphology on the peripheral blood film. In thalassemias, the Hb concentration and the mean corpuscular volume (MCV), an index of cell size, are decreased, sometimes markedly, whereas in hemoglobinopathies both are often normal. One study recommends that an MCV of less than 72 fL (reference interval ~80 to 100 fL)[99] is maximally sensitive and specific for the presumptive diagnosis of thalassemia. However, the use of an MCH (mean corpuscular hemoglobin) value less than 27 pg (reference interval ~26 to 35 pg)[119] has been recommended as the decision point to further investigate for iron deficiency anemia and thalassemia. The rationale for the selection of MCH over MCV as the decision point for further investigation is the potential increase of up to 5 fL in MCV in samples more than 24 hours old.

The RBC is either in the upper half of or above the reference interval in thalassemias but within the reference interval in most hemoglobinopathies without a coinherited thalassemia. In contrast the RBC is low in iron deficiency anemias and anemia of chronic disease and is proportionally related to the decrease in Hb concentration. The red cell distribution width (RDW), a measure of the variation in the size of the RBC (anisocytosis), tends to be above the reference interval in iron deficiency anemias and other microcytic anemias. The RDW in thalassemias is usually within the reference interval, reflecting the uniformity of the red cell size. However, in Hb H disease and δβ-thalassemia the RDW is moderately increased.



In thalassemias the RBCs in the peripheral blood smear are hypochromic and microcytic. The characteristic sickle or crescent-shaped RBCs are seen (Figure 31-9) in the peripheral blood smear of patients who are homozygous for Hb S (sickle cell disease) and target cells are seen in blood smears from patients who are homozygous for Hb E (Figure 31-9) and Hb C. In addition, lip cells and crystalline inclusions (Hb C cells) may be found in peripheral blood smears from individuals who are homozygous for Hb C. These findings are less uniformly present than the typical morphological features of sickle cell disease.

There are several formulas, using parameters from the CBC, to calculate a thalassemic index used to differentiate iron deficiency from thalassemia.[99] Although none have proved to be totally satisfactory in all clinical situations and may not add significant information over the use of the MCV alone in selecting cases for further investigation, many laboratories use these calculations as an adjunct to the CBC parameters. One such formula[72] is

$$\text{Discriminant Factor (DF)} = (\text{MCV} \times \text{MCV}) \times \frac{\text{RDW}}{\text{Hb}} \times 100$$

A DF of <65 is associated with thalassemia minor and a value >75 is associated with iron deficiency anemia. Values between 65 and 75 are classified as equivocal and may indicate a combined iron deficiency anemia with an underlying thalassemia.

The CBC parameters are very often the first indication that the patient might have either a thalassemia or a hemoglobinopathy however, these data are not sufficient to make even a presumptive diagnosis. In addition; the iron status of the patient, as measured with either ferritin or iron/iron

Homozygous E (a) Homozygous S (b)

Figure 31-9 Peripheral blood smear from patients with homozygous Hb E (a) and homozygous Hb S (b).

binding/saturation index tests (see the next section), can help in differentiating iron deficiency anemia from anemia of chronic disease and thalassemia. However, ferritin is elevated in acute phase reactions, and iron deficiency can mask an underlying thalassemia.

An algorithm[126] based on the MCV, MCH, Hb A_2, and Hb F quantifications has been advocated to better discriminate between β-thalassemia minor, iron deficiency, δβ-thalassemia, and hereditary persistence of fetal hemoglobin (HPFH).[131]

Electrophoresis

Electrophoresis (see Chapter 5) under alkaline conditions (pH 9.2) is the most common initial screening method for the detection and preliminary identification of hemoglobinopathies. Several media, including paper and cellulose acetate, have been used although agarose[119] is now the medium of choice and the one usually supplied commercially. A pH 9.2 barbital buffer is the most common buffer system. Visualization of the separated Hb bands is achieved by using a protein-binding stain, such as Amido Black or Ponceau S. Hemoglobin bands stain blue with Amido Black and reddish pink with Ponceau S. Following clearing of excess stain, the Hb bands on the agarose media are clearly seen against the clear background. Figure 31-10 shows an alkaline electrophoresis gel stained with Amido Black. Quantification by densitometry of the Hb A_2 and F bands on alkaline electrophoresis, although commonly performed by laboratories, is not recommended by the College of American Pathologists in the hemoglobinopathy survey critiques[98] because of high analytical imprecision resulting from limitations of densitometry in measuring low levels of staining.

The Hbs migrate according to electrical charge, with Hb H moving the fastest (closest to the anode). The order of migration (fastest to slowest) is Hb H, Hb N, Hb I, Hb J, Hb A, Hb F, Hb S, and Hb C. Hemoglobins D and G co-migrate with Hb S, and Hbs E, O, and A_2 co-migrate with Hb C. Hemoglobin Constant Spring migrates slightly toward the cathode.

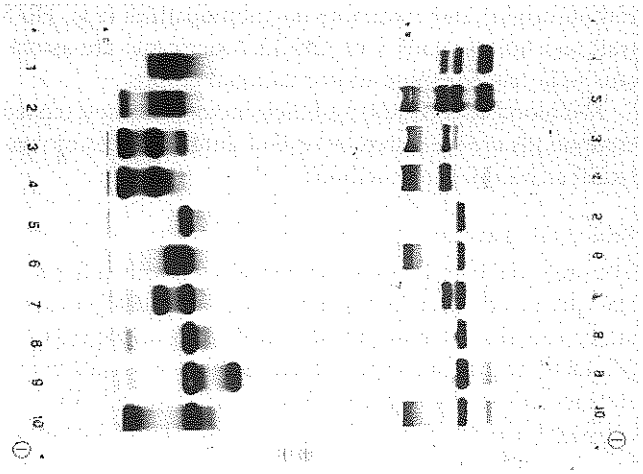


Figure 31-10 Alkaline and acid electrophoresis of various hemoglobinopathies. Lane 1, Hb S, Hb FA control; Lane 2, HB S, Hb F, HbCA control; Lane 3, transfused SC disease; Lane 4, SC disease; Lane 5, Hb A (normal); Lane 6, Hb Presbyterian; Lane 7, Hb S; Lane 8, raised Hb A_2 (β-thalassemia trait); Lane 9, Hb J Baltimore; Lane 10, Hb C.

Electrophoresis at pH 6.4 using a citrate buffer is performed when an abnormal band is noted on alkaline Hb electrophoresis. Agarose is the preferred medium, with Acid Violet the preferred stain. Figure 31-10 shows the same Hb variants performed on agarose electrophoresis at pH 6.4 and stained with Acid Violet. The order of migration (cathode to anode, fastest to slowest) is Hb F, Hb A, Hb S, and Hb C. Hemoglobins D, G, I, J, O, A_2, and E co-migrate with Hb A.

Based on positions of the bands in acid and alkaline electrophoresis, a presumptive identification of the Hb variant may be made. For example, bands are found on alkaline electrophoresis in both A and C positions. On acid electrophoresis if bands are found in the A and C positions, then a presumptive identification of Hb C trait may be made, as

this pattern is characteristic. However, if a band is found only in the A position on acid electrophoresis, then a presumptive identification of Hb E may be made. If bands are found in the C position on alkaline electrophoresis and between the S and A positions on acid electrophoresis, then a presumptive identification of Hb O may be made. Further testing is required to determine if the Hb O is Hb O Arab, O Indonesia, or O Padova. Fairbanks[56] described a numbering system for the most common Hb bands on alkaline electrophoresis (Hb H = 1, Hb A = 5, Hb S = 9, Hb C = 13) that allowed the position of a band to be described more exactly than the commonly used descriptive term "between S and A positions." Unfortunately, this system has not found universal acceptance. Laboratories should keep a bank of electrophoretic data obtained to help in future identification of unusual Hb variants

Specific types of electrophoresis that are used for Hb analysis include isoelectric focusing, electrophoresis, and capillary electrophoresis.

Isoelectric Focusing Electrophoresis. Isoelectric focusing electrophoresis (IEF)[34,170] has higher resolving power than conventional electrophoresis, but is more expensive, time consuming, and technique dependent to perform (see Chapter 5). Commercial IEF gels are made of cellulose acetate or polyacrylamide with the pH gradient produced by the inclusion of amphoteric materials of different pH values in bands in the gel. Locations of the Hb bands are identified using stains similar to those used in conventional electrophoresis. The bands or zones produced by IEF (Figure 31-11) are better defined than conventional electrophoresis, and reliable quantification of the separated Hbs at high concentrations using densitometry may be made. Quantification of Hb A_2 and Hb F at low concentrations, however, is imprecise and not recommended. The Hb elution pattern in IEF is similar to that of alkaline Hb electrophoresis except that Hb D and Hb G are resolved from each other and from Hb S. Historically, IEF has been used extensively to identify and characterize Hb variants; however, it is less used now because of the previously mentioned limitations.

Capillary Isoelectric Focusing Electrophoresis. Capillary isoelectric focusing electrophoresis* combines the detection sensitivity of capillary electrophoresis (see Chapter 5) with the resolution qualities and existing extensive data on Hb variant separation by immunoelectrophoresis (IEP) and the automated sampling and digital data acquisition techniques developed for chromatography. With it, the hemolysate is introduced into the capillary chamber using low pressure injection and then focused at high voltage (typically ~30 kV and 0.5 to 1.5 μA) during which it is essential to maintain adequate cooling. The separated Hbs are then eluted, using low-pressure and simultaneous voltage, past either a single wavelength spectrophotometric detector set to read at 415 nm or a dual wavelength detector set at 415 and 450 nm. In routine use, the Hbs are typically separated within 15 minutes, but the elution time may be extended if the presence of abnormal Hb is suspected. Hb variants[77] are identified by comparison of the isoelectric point (pI) values and migration times of the unknown, using Hb A as the reference peak, with known controls and published data. Quantification is based on the integration of the measured absorbance of the bands, and accurate results have been obtained for Hb A_2 and Hb F concentrations.

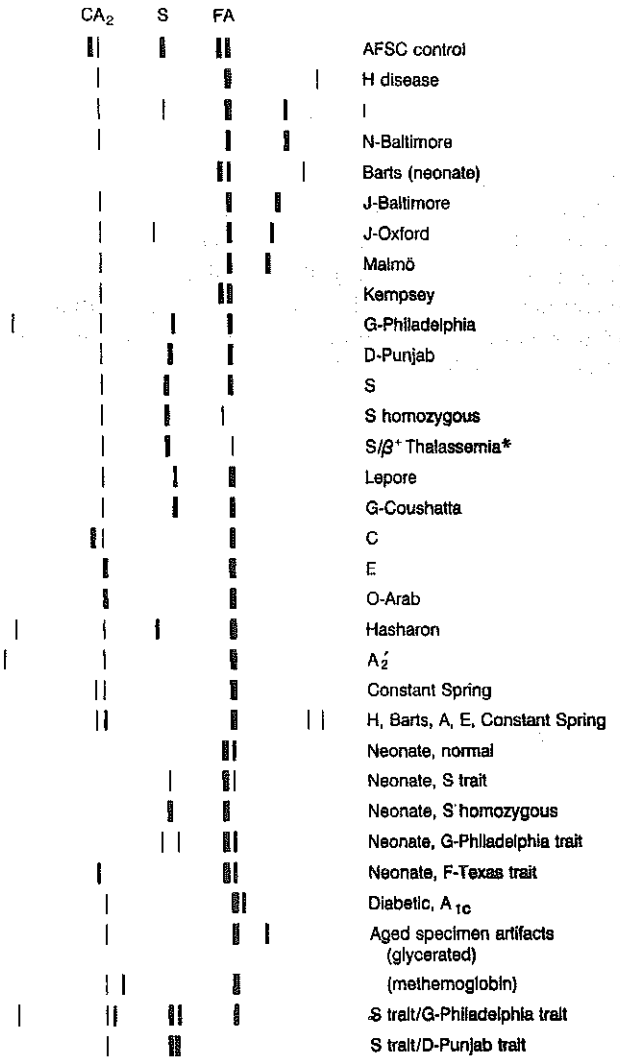

Figure 31-11 A diagram of isoelectric focusing patterns for a variety of Hb variants. The conditions shown represent heterozygotes (traits) unless otherwise indicated. The width of the bars approximates the relative density of the bands observed. The acid anodic (pH 6) side is to the right, and the alkaline cathodic (pH 8) side is to the left. The same pattern is observed in homozygous patients with Hb S disease who have received Hb A by transfusion.

High-Performance Liquid Chromatography

HPLC using a column packed with cation-exchange resin[68,130-133,145,170] provides, in a single analytical protocol, the quantification of Hbs F and A_2 (see Chapter 6 for a detailed

discussion of HPLC). With it, the initial identification of an Hb variant on the basis of the elution time may be made. It has also been used to detect α-thalassemia phenotypes.

After injection and subsequent adsorption onto the particles of cation-exchange resin, molecules of Hb are eluted using gradient elution. Detection of the eluted Hbs is achieved by monitoring the effluent solvent stream using a dual wavelength photometer (usually set to measure at wavelengths of 415 and 690 nm). The technique is precise for the quantification of both Hb F and Hb A_2, and presumptive identification of the common Hb variant may be made. These features have made HPLC the method of choice for hemoglobinopathy and thalassemia screening for many laboratories including those performing neonatal hemoglobinopathy screening. Figure 31-12 shows the separation on a commercial system of several Hb variants.

Several commercial methods are available but lack the resolution achieved by noncommercial methods. A noncommercial HPLC method has been described with the retention time and relative concentration of 40 common Hb variants listed.[130] This system requires a longer time of analysis, provides superior resolution, and overcomes the problem of co-elution of several Hb variants that occurs with commercial systems. For example, with one commercial system, Hbs E, Osu-Christianborg, G-Coushatta, Lepore, and G-Copenhagen co-elute with Hb A_2, making Hb A_2

Laboratory Investigation of Hemoglobinopathies and Thalassemias: Review and Update. Clin Chem 2000;46: 1284-90.)*

quantification and definitive identification of the Hb variants impossible.[44]

Other chromatographic problems, such as a rising baseline, have resulted in Hb A_2 concentration being falsely low in Hb D patients.[47,155] However, this may be corrected mathematically to produce a more accurate result. Patients with Hb S have falsely increased Hb A_2 concentrations caused by the co-elution of glycated Hb S with Hb A_2.[166] Diagnosis of co-inheritance of β-thalassemia with Hb S, a combination that is not unusual, may be compromised by this false increase in Hb A_2. However, knowledge of the concentration of Hb A_2 is not essential in making the diagnosis of β^0- or β^+-thalassemia in these patients. In a case of β^0 thalassemia (β-thalassemia major) no δ-globin chain is produced, and the electrophoretic pattern and HPLC closely resemble those of a homozygous Hb S patient (large Hb F and Hb S peaks with no Hb A peak). In β^+-thalassemia (β-thalassemia intermedia), the concentration of Hb S is greater than that of Hb A, a situation that is only seen otherwise in recently transfused patients who have sickle cell disease. Co-inheritance of β-thalassemia minor and Hb S may be diagnosed in these patients by setting the upper limit of the reference interval at 5.0%.[82] Capillary zone electrophoresis and microcolumn methods have been described that eliminate the interference of glycated Hb S with Hb A_2 quantification.

The use of relative elution time rather than absolute elution time in initial identification of an unknown Hb variant is useful and recommended.[145] The reference Hb ideally is one that is found in low concentrations in most individuals. In this regard Hb A_2 is probably the most useful as a reference point despite the number of co-eluting Hb variants.

The elution time of the Hb may change slightly with increasing Hb variant concentration. For example, Hb F concentrations obtained by HPLC are often lower than those from the alkaline denaturation and/or spectrophotometric methods that are often quoted in standard hematology texts and used for the diagnosis of juvenile myelomonocytic leukemia (JMML) and monosomy 7 syndrome. However, caution should be used in interchanging Hb F concentrations obtained by HPLC with other methods.

It should be noted that hemoglobinopathies may interfere with glycated hemoglobin (GHb) analysis, as results may be falsely increased or decreased, depending on the particular method and the hemoglobinopathy.[30,154] Hemoglobin variants that cannot be separated from Hb A or Hb A_{1c} will produce spuriously increased or decreased results by ion-exchange HPLC.

Electrospray Mass Spectroscopy

Electrospray mass spectrometry (see Chapter 7) is becoming the method of choice for the complete characterization of newly discovered Hb variants.[19-21,143] With it, the mass of the variant, whether the variant is an α- or β-chain variant, the possible location and identity of the amino acid residue substitution, and the quantity of variant present may be derived.

To analyze a sample with this technique, the globin chains are first separated by conventional methods and then isolated by semipreparative HPLC. The isolated fractions are further concentrated using a variety of techniques including membrane filtration. The fraction containing the mutant globin chain is digested using specific endopeptidases that selectively cut at certain amino acid residues of the globin chain. The resultant digested peptide fragments are further separated by preparative HPLC and the mutant peptide sequenced using Edman degradation. Another portion of the digested globin chains is entered into the electrospray mass spectrometer, and the resultant mass spectrum provides information on the mass of the mutant globin chain, which can be then used to provisionally identify the substituted amino acid. For Hb Rambam,[20] the mass spectrum of the β-globin chains shows the mass of the normal β-chain to be 15,867 Da and the mass of the mutant β-chain to be 15,925 Da. The increase in mass of 58 in the mutant β-globin chain may be attributed to a change in amino acid residue from glycine (MW 75 Da) to aspartic acid (MW 133 Da).

DNA Analysis

DNA analysis is used in the investigation of thalassemias and hemoglobinopathies to identify, in populations with a known high incidence of disease, those specific individuals at risk and who may benefit from genetic counseling. For example, DNA analysis has been used to:

1. Diagnose α^0- and α^+-thalassemia[8,26,177]
2. Investigate potentially life-threatening disorders of Hb synthesis in the fetus and is performed at less than 10 weeks gestation on chorionic villus[126] samples
3. Characterize the β-thalassemia genotype*
4. Screen at-risk populations for clinically significant Hb variants[69,159]
5. Distinguish between conditions that have similar, laboratory, and clinical presentation but are due to different genetic conditions[123]

The Southern blot analysis of genomic DNA using α- and ζ-primers is widely used in the investigation of α-thalassemias, especially in the identification of individuals with α^0-thalassemia. Polymerase chain reaction (PCR), using allele-specific primers, is used by reference laboratories in the identification of common β-thalassemia mutations and some hemoglobinopathies. Gene sequencing information may supplement these techniques in some cases.

Specific Tests

Tests that are used to measure Hbs and related analytes include those for Hb H, Hb S, unstable Hbs, and globin chains.

Determining Hemoglobin H

Hb H is an insoluble tetramer consisting of four β-globin chains and arises in α-thalassemia in which there is a

*References 69, 79, 83, 105, 157, 176.

decreased production of α-globin chains caused by nonexpression of three of the four α-globin genes and a subsequent excess of β-globin chains. If these tetramers are oxidized, precipitation occurs, which may be viewed microscopically. In the laboratory, this oxidation is achieved by staining unfixed cells with new methylene blue or brilliant cresyl blue at 37 °C. The inclusion of positive and negative controls with each batch of Hb H preparations is essential because there is substantial batch-to-batch variability in the dye.[74] There is controversy on the necessity to perform this test on freshly collected blood and whether the test should be performed on all suspected α-thalassemia cases.

In Hb H disease, 30% to 100% of the red cells contain inclusions, which have been described as looking like "golf balls" (Figure 31-13). In α-thalassemia minor (one functional α-gene) as few as 1 cell with inclusions per 1000 to 10,000 red cells may be seen, and the diagnosis of α-thalassemia minor cannot be definitively made in the absence of Hb H inclusions. The presence of Hb H inclusions may serve as confirmation of a presumptive diagnosis of α^0-thalassemia (α-thalassemia major) or Hb H disease.

Precipitate patterns resembling Hb H inclusions may arise from staining of reticulin and Howell-Jolly bodies and other protein and nucleic acid entities. Hb H inclusions may also be very rare and difficult to detect when there is increased reticulocytosis.

Hb H detection by this method is laborious to perform and is quite subjective. However, for the detection of the two α-gene *cis* deletion (−/αα) of α^0-thalassemia, the test is reported to have a clinical sensitivity of 0.47 and a specificity of 0.99.[100]

Sickling Tests

Sickling tests are useful in confirming the presence of Hb S in a sample following initial electrophoresis at alkaline pH. When fully oxygenated Hb S is fully soluble but when deoxygenated, polymerization occurs, forming insoluble tactoids, which deform the red cells in a characteristic rigid sickle shape. In the laboratory, deoxygenation and lysis of the RBCs is achieved by the use of a solution of sodium metabisulfite in a phosphate buffer. The addition of the sodium metabisulfite reagent to an Hb S–containing blood sample causes turbidity. This turbidity is visualized by holding a lined card or a card with writing on it behind the reaction test tube (Figure 31-14). In positive samples lines or letters cannot be seen whereas in negative samples lines or letters are clearly visible. Both a positive and negative control should be performed with each test. The hematocrit of the blood sample to be tested should be measured and if less than 15% the amount of blood used in the test should be doubled because a low Hb concentration is a demonstrated cause of falsely negative sickling screens. Lipemic samples and samples with a monoclonal protein (M-protein) may give a false-positive result. Hb C Harlem and Hb Memphis ($\alpha 23(B4)^{Glu \rightarrow Gln}$) also give a positive result in this procedure and therefore it is essential to identify the Hb present in all positive tests by other techniques. The test is quite subjective and the combination of two identification techniques, such as HPLC and alkaline electrophoresis, may eliminate the necessity to perform this test on a routine basis.

Tests for Unstable Hemoglobins

These tests use either heat or isopropanol to precipitate the unstable Hb and must be performed on fresh blood. There are more than 100 unstable Hbs resulting mainly from the interchange of nonpolar amino acid residues for polar amino acid residues in positions in either the α- or β-globin chain associated with the heme cleft. Hb Hasharon ($\alpha 47(CD)^{Asp \rightarrow His}$), an Hb variant found in Ashkenazi Jews,

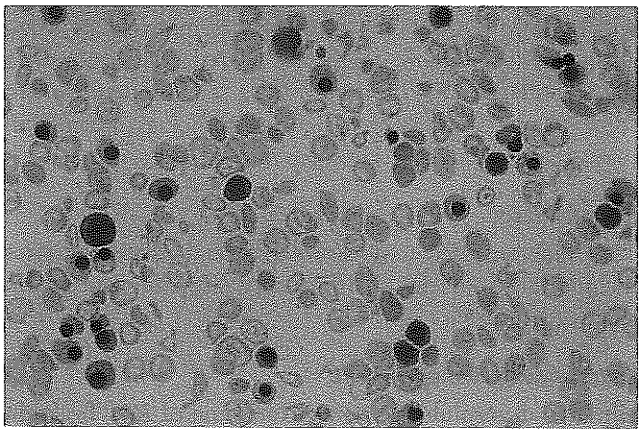

Figure 31-13 Peripheral blood smear of an individual with β^0-thalassemia. *(Courtesy Dr. G. Clarke, Dynacare Kasper Medical Laboratories.)*

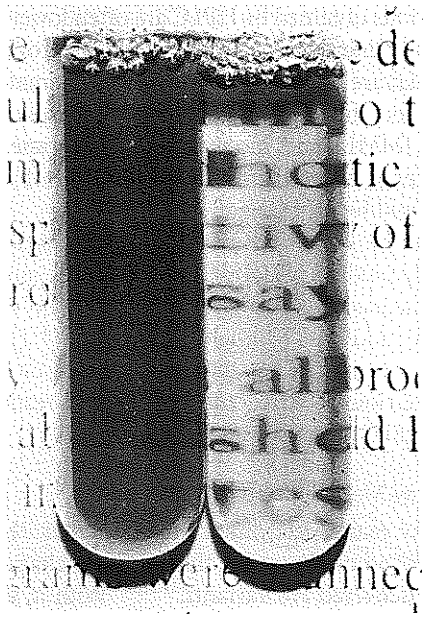

Figure 31-14 Solubility test for Hb S. Deoxyhemoglobin S *(left tube)* is insoluble in 2.3 mol/L phosphate buffer. By contrast, normal hemolysate *(right tube)* is sufficiently transparent that print can easily be read through it.

results from the substitution of the nonpolar amino acid residue histidine for the polar aspartic acid residue at position 47 of the α-chain. In conventional nomenclature, Hb Hasharon should be written as $\alpha 47(CE5)^{Asp \rightarrow His}$; however, to maintain uniformity with the β-, γ-, and δ-globin chains the term CD is used to designate the corresponding interhelical segment of the α-chain, which does not have a D segment.

Nonpolar isopropanol weakens the internal bonds within Hb, decreasing the stability of the Hb molecule. Normal hemoglobin (Hb A) precipitates within 40 minutes at 37 °C in the presence of a 17% solution of isopropanol in a pH 7.4 TRIS buffer. Unstable Hbs usually precipitate within 5 minutes under these conditions. Both a positive and negative control should be included with each analysis, although a positive control may not always be readily available. An umbilical cord blood or neonatal sample, not fresh, may be an acceptable alternative as a positive control. At the time of reading, the negative control should be clear, and the positive control should have some flocculation.

Normal Hb is stable when heated to 50 °C. However, unstable Hbs precipitate to varying extents when similarly treated. A hemolysate of the sample in a pH 7.4 TRIS-phosphate buffer is divided into two aliquots. One is stored at 4 °C, the other is heated at 50 °C for 2 hours. Both samples are then centrifuged and Hb quantification is performed on each supernatant. The quantification of the unstable Hb is calculated using the following formula:

$$\%\ \text{Unstable hemogobin} = \frac{\text{Hb}(4\,^{\circ}\text{C}) - \text{Hb}(50\,^{\circ}\text{C})}{\text{Hb}(4\,^{\circ}\text{C})} \times 100$$

Frequently, both heat and isopropanol stability tests are performed when a suspected unstable Hb variant is investigated. Unstable Hb variants may not appear on HPLC or electrophoresis, especially if the variant is unstable enough to precipitate before analysis by these techniques.

Globin Chain Analysis

In this analysis, the globin chains and heme in a red cell lysate are first dissociated using urea and dithiothreitol. The dissociated globin chains are then separated electrophoretically at both an alkaline and acid pH (Figure 31-15). HPLC may also be used for separation. Globin chains are identified by comparison of retention times and/or electrophoretic mobility with known reference materials or published data. Globin chain analysis is an adjunct to methods described earlier and in many laboratories has been discontinued and replaced with either HPLC or capillary isoelectric focusing.

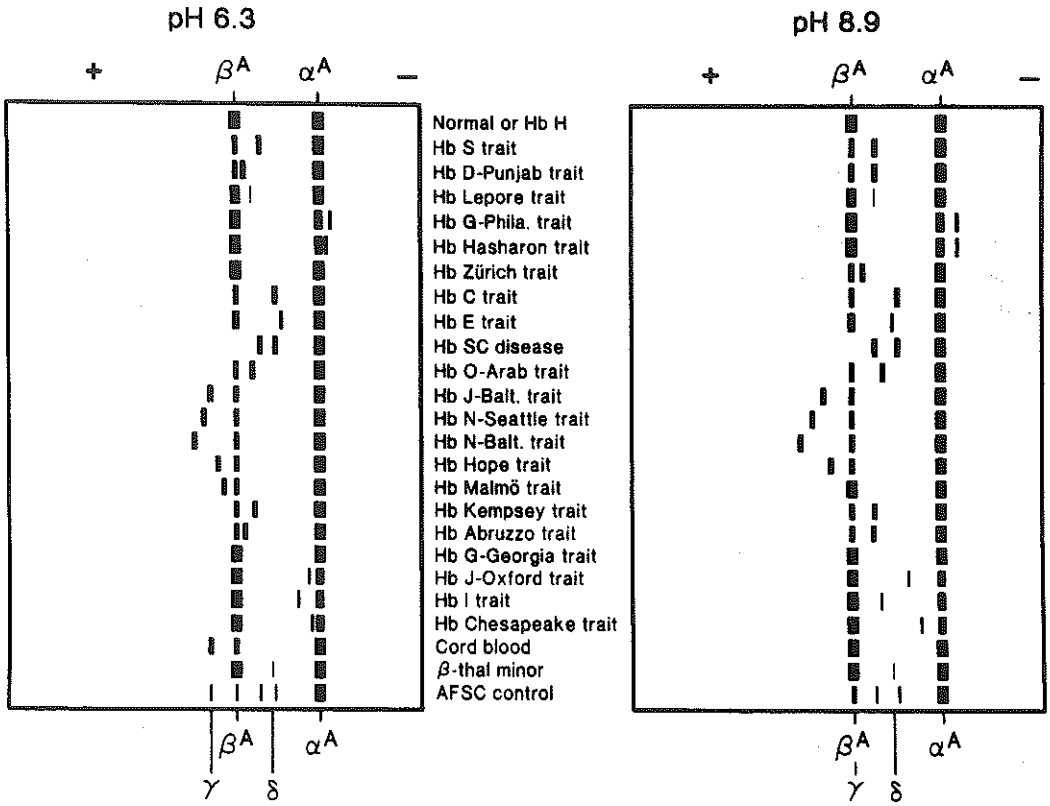

Figure 31-15 Comparison of electrophoretic mobilities of globin chains derived from Hb variants in urea buffers, 8 mol/L. The *left panel* shows separation at pH 6.3, and the *right panel* shows separation at pH 8.9. Results are shown for all common and some uncommon Hb variants. Because most of the variants are in specimens from people who are heterozygotes, the normal β^A- and α^A-globin chains are also present and serve as position markers.

Clinical Significance

The thalassemias and hemoglobinopathies are clinical disorders related to Hb pathophysiology. Although they may have similar clinical manifestations,[44] such as anemia of varying severity, they form two distinct disease groups of genetic origin. For example, the thalassemias originate from insufficient globin chain production instigated by a variety of causes, including gene deletion, nonsense mutations, or from mutations that affect the transcription or stability of mRNA products. The name thalassemia is derived from the Greek word for sea, *thalassa,* because all the early cases of β-thalassemia were described in children of Mediterranean origin.

Hemoglobinopathies, the most common single gene disorder in the world, are structural Hb variants arising from mutations in the globin genes, which result in substitutions or disruptions in the normal amino acid residue sequence in one or more of the globin chains of Hb.

Thalassemias

Thalassemias are identified by the globin chain in which there is a production deficiency. For example, α- and β-thalassemias result from a deficiency in α- and β-globin chain production, respectively. They are further classified depending on the extent of globin chain production and the resultant severity of the anemia.

α-Thalassemias

The α-thalassemias arise from deficiencies in the production of the α-globin chains and are caused by deletions or (less frequently) point mutations in one or more of the four α-globin genes. By convention, the term α^0-thalassemia is used when the two deleted α-globin chain genes are in the same gene cluster. This is sometimes described as a *cis* deletion and is written as (–/αα). The term α^+-thalassemia is used when the two deleted α-globin chain genes are on opposite gene clusters. It is sometimes described as a *trans* deletion and is written (–α/–α). A single α-gene deletion (αα/–α) is called α-thalassemia trait or α-thalassemia minor. Point mutations are much less frequent, currently numbering less than 40. The conventional nomenclature for these point mutations α-thalassemias is $\alpha^T\alpha$ or $\alpha\alpha^T$. The α-thalassemias range in clinical presentation from conditions that are incompatible with life to slight anemia or clinically and hematologically single-gene silent deletions. The severity of the anemia reflects the number of deleted genes. The α-thalassemias occur worldwide and are particularly prevalent in South East Asia, Southern China, Mediterranean countries (particularly Greece and the Greek Cypriot part of Cyprus), India, the Middle East, and the islands of the South Pacific.

Individual types of α-thalassemias are discussed below.

Hb Bart's. Hb Bart's results from deletion of all four α-globin genes with the subsequent inability to produce any α-globin chains that leads to failure of synthesis of Hbs A, F, or A_2. In the fetus there is an excess of γ-globin chains that join together to form unstable tetramers known as Hb Bart's (γ^4). Mothers carrying a fetus with Hb Bart's usually present clinically between 20 and 26 weeks gestation with pregnancy-induced hypertension and polyhydramnios. Ultrasound of the fetus shows hydrops. Severe anemia (Hb usually <80 g/L) is noted on a fetal blood sample obtained by cordocentesis. It is important to rule out other causes for the hydropic fetus by performing TORCH (*to*xoplasmosis, *r*ubella, *c*ytomegalovirus, and *h*erpes simplex) testing.

HPLC analysis of a cordocentesis blood sample shows one or two very sharp and narrow peaks at the injection point on the chromatogram (Figure 31-12, *a*). The major band is Hb Bart's with a smaller band attributed to Hb Portland. There is a complete absence of Hb F. Alkaline electrophoresis shows a band migrating at or close to the solvent front (Hb Bart's) with another band in the Hb A position (Hb Portland).

Hb Bart's hydrops fetalis is almost invariably fatal,[43] with some fetuses dying in utero and others surviving a few hours after birth. Treatment using intrauterine transfusion has had very limited success, with potential complications in the children of growth retardation and severe brain damage, which may possibly be related to long-standing intrauterine anemia.

Laboratory investigation of the parents of fetuses with Hb Bart's shows a normal HPLC pattern with normal Hb F and A_2 quantification. Parental analysis typically shows a decreased level of Hb, decreased MCH, and MCV with the blood smear showing hypochromic, microcytic red cells. The Hb H test may be positive in one or both parents. A two α-gene *cis*-deletion (–/αα) or three gene deletion (–/–α) is seen in genetic testing of both parents. This requirement restricts the incidence of Hb Bart's to a much smaller population than would be expected based on the worldwide distribution of two α-gene deletions, as the presence of *trans* deletions in both parents would not give rise to a four gene deletion in the offspring. Hb Bart's is relatively common in South East Asia, particularly in Thailand, the Philippines, and Hong Kong where there is a high prevalence of the $--^{SEA}$ deletion.

Hb H Disease. This disorder is usually caused by a three α-globin gene deletion (–/–α) and is characterized by a chronic anemia of variable severity. Individuals with the nondeletional Hb H disease ($\alpha^T\alpha$/–) are usually more severely affected and are more likely to require transfusion therapy than those with the deletional Hb H disease. There is a significant underproduction of α-globin chains and subsequent joining of free β-globin chains to form the insoluble β-globin chain tetramer Hb H. HPLC analysis of a hemolysate from an individual with Hb H disease shows two bands with low retention times forming a doublet together with a normal Hb A band. Hb F and Hb A_2 concentrations are within the reference interval (Figure 31-12, *d*). Electrophoresis at alkaline pH shows a fast moving band together with a band in the Hb A position that possibly has reduced staining when compared with other samples run concurrently. The CBC shows a moderately reduced level of Hb, and

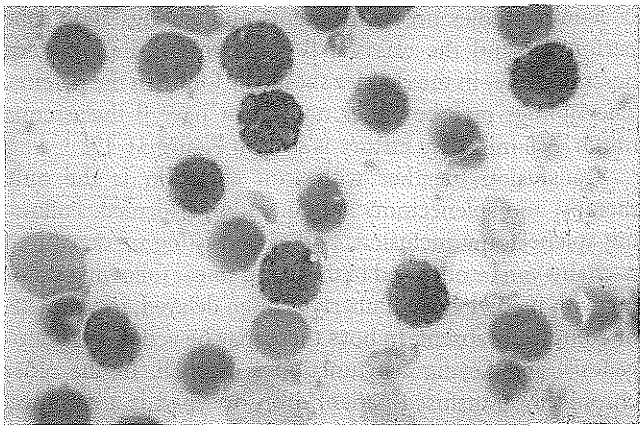

Figure 31-16 Hb H preparation showing punctate inclusions on a patient with Hb H disease.

markedly reduced MCV and MCH with slightly raised RBC count. Iron studies are normal although the ferritin may be raised. The Hb H preparation is positive, with many cells with typical punctate inclusions (Figure 31-16).

Iron therapy is not indicated, and transfusion therapy is usually unnecessary except in acute illness, in pregnancy, and with exposure to oxidant drugs, which destabilizes Hb H, causing precipitation of the somewhat insoluble protein. Genetic counseling is recommended to prospective parents who have Hb H disease.

α-Thalassemia Major. α-Thalassemia major is the result of a two α-chain gene deletion. These deletions may be on the same gene (–/αα, α^0-thalassemia) described as a *cis* deletion or on different genes (–α/–α, α^+-thalassemia) described as a *trans* deletion. The CBC of affected individuals shows a mildly reduced level of Hb with low MCV and MCH. HPLC analysis shows no abnormal Hb peaks and the Hb F and Hb A_2 concentrations are within the reference interval. Hb H preparation may show a rare cell with punctate inclusions. Iron studies are normal. In the routine clinical laboratory, the diagnosis of α-thalassemia major is based on exclusion criteria rather than definitive tests. The presence of thalassemic indices in a patient with normal Hb A_2 and Hb F quantifications is very often the only basis for many diagnoses of α-thalassemia major, particularly in the setting of a positive family history. A photometric enzyme-linked immunosorbent assay (ELISA) for the identification of adult carriers of the ($-^{SEA}$) α^0-thalassemia deletion has been described.[100] This method is based on the measurement of minuscule amounts of embryonic ζ-cells present in these adult carriers. Not all α-thalassemia deletions have continued ζ-chain production and so a negative test is not diagnostic of α-thalassemia major. This test could be useful in screening individuals at risk for giving birth to a fetus with Hb Bart's hydrops fetalis.

α-Thalassemia Trait. α-Thalassemia trait describes a single α-globin chain gene deletion (–α/αα). A single α-globin gene deletion is frequently clinically and hematologically silent. A CBC of an individual with this trait shows a normal or marginally decreased Hb level, MCV, and MCH. Iron studies are normal, and no abnormal Hb peaks are seen on HPLC analysis.

β-*Thalassemias*

The β-thalassemias result from a reduction in the synthesis of the β-globin chain[127] and are commonly found in the Mediterranean region, Africa, the Middle East, South East Asia—especially the Southern provinces of China including Hong Kong, the Indian subcontinent, the Malay peninsula, Burma, and Indonesia.[179] Frequency of gene distribution is estimated at 3% to 10% in some populations. The high frequency of β-thalassemia in the tropics is thought to reflect an advantage of heterozygotes against *Plasmodium falciparum* malaria. More than 200 β-thalassemia mutations have been described; however, in each ethnic group a relatively small number of mutations account for the majority of cases (the ratio most often quoted is 20 or fewer mutations account for 80% or more of the cases). Clinical manifestations of β-thalassemia range from mild anemia to severe life-threatening disease requiring lifelong transfusions.

β^0-Thalassemia (β-Thalassemia Major). Sometimes called Cooley's anemia after the physician[181] who in 1925 first described the condition in the children of Italian and Greek immigrants in New York by noting that these children failed to grow, had frequent infections, appeared pale and malnourished, had splenomegaly, and had facial bone changes.

β-Thalassemia major results from mutations that interfere with translation or are involved in the initiation, elongation, or termination of globin chain synthesis. Mutations that interfere with translation account for almost 50% of all the β-thalassemia mutations. Included in this are frame shift or nonsense mutations that produce premature termination codons that result in incomplete translation of the β-globin gene and nonproduction of the β-globin chain resulting in β^0-thalassemia.

Clinical presentation is usually at less than 1 year of age with features that include small size for age, abdominal girth expansion, and failure to thrive. Physical examination of the subject may reveal frontal bossing[146] (a rounded eminence on the forehead) caused by thickening of the cranial bones, pallor, and prominence of the cheek bones, which, in older children, obscures the base of the nose and exposes the teeth. These features are a result of marrow expansion (up to a thirtyfold increase) caused by ineffective erythropoiesis with production of highly unstable α-globin tetramers leading to increased plasma volume and the formation of extramedullary erythropoietic tissue, especially in the thorax and paraspinal region. The spleen, liver, and heart may be enlarged also because of extramedullary hematopoiesis.

Typical CBC results include severe anemia with the Hb concentration between 30 and 65 g/L, MCV 48 to 72 fL, and the mean corpuscular hemoglobin concentration (MCHC) 230 to 320 g/L. On the peripheral blood smear, a characteristic markedly abnormal RBC morphology is noted, which includes a large number of microcytes, numerous target

cells, which may have a bridge joining the central and peripheral pigment zones, polychromasia and occasional spherocytes, schistocytes, and nucleated red cells. Anisocytosis is noted, the diameter of the RBC ranges from 3 to 15 μm with little pigment, and there is shape distortion. Prominent basophilic stippling is noted. RBC osmotic fragility is frequently observed. A typical peripheral blood on a patient with β^0 thalassemia is shown in Figure 31-16.

The white blood cell (WBC) and platelet counts are usually normal. Ferritin is usually within the upper half of the reference interval, and the total bilirubin is mildly elevated with a borderline elevation in the conjugated fraction. Urinalysis frequently shows increased urobilinogen or urobilin concentration and is often colored dark brown to black because of the presence of dipyroles and mesobilifuscin. The latter features reflect ineffective hematopoiesis with intramedullary red cell destruction. HPLC analysis (Figure 31-12, *b*) shows a major Hb F peak with an absence of an Hb A peak and variable Hb A_2 (range 1% to 5.9%, mean 1.7%) peak. Electrophoresis at alkaline and acid pH shows a dominant band in the F position on both gels.[7]

Family studies on both parents and siblings should be performed and the classical β-thalassemia minor pattern described later in the chapter should be found in the parents. The siblings may be either normal or have β-thalassemia minor. A family case history is seen in Figure 31-17.

Transfusion together with iron chelation is the only therapy, and splenectomy is frequently performed. Following splenectomy inclusion, bodies consisting of denatured α-chains can be observed in the blood smear following staining with methyl violet. Puberty is often delayed, incomplete, or completely absent. In boys there may be active spermatogenesis, and Leydig cell function is normal. In the older chronically transfused patient, iron overload is a common feature. Diabetes mellitus and hypoparathyroidism are frequent sequelae. Numerous cardiopulmonary conditions, including pericarditis and myocardial hemosiderosis, are the leading causes of death in transfused patients, and are frequently associated with β^0-thalassemia.

β^+-Thalassemia (β-Thalassemia Intermedia). With this disorder, there is a significant reduction in the production of β-globin chain with subsequent reduction in the quantity of Hb A present, which is attributed to a wide variety of geno-

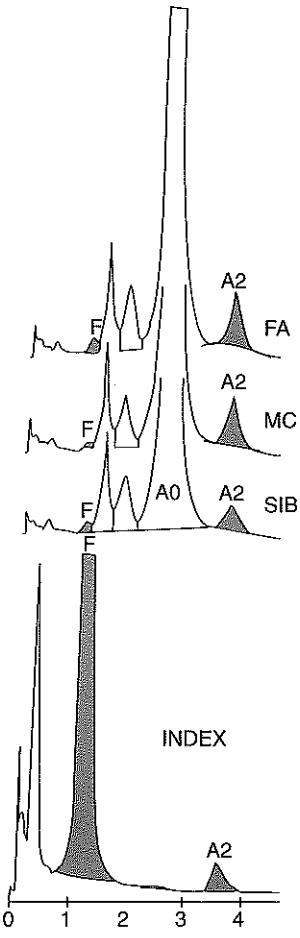

Figure 31-17 HPLC chromatograms and CBC results from a family study of a child with B^0-thalassemia. *(From Berendt HL, Blakney GB, Clarke GM, Higgins TN. A case of β-thalassemia major detected using HPLC in a child of Chinese ancestry Clin Biochem 2000;33:311-13.)*

types. There are many different causes for β^+-thalassemia, with variations in one or two β-globin genes. The clinical severity in individuals with variations in two β-globin chains is much less than when there is a variation in only one gene, a condition sometimes called dominant β-thalassemia. There is a reduction in the severity of the clinical features with the coinheritance of α-thalassemia. β^+-thalassemia is found in Mediterranean countries, especially in the Eastern Mediterranean.

Clinical presentation varies from symptoms similar to β^0-thalassemia to those associated with β-thalassemia trait. Transfusions are usually not necessary, and hydroxyurea therapy is frequently used to increase the production of Hb F and to mitigate disease symptoms.

HPLC analysis shows a large Hb F peak with a reduced Hb A peak. Hb A_2 is above the reference interval at concentrations greater than those associated with β-thalassemia minor. Bands in the A and F positions are seen on electrophoresis at both alkaline and acid pH. The Hb is significantly reduced (60 to 100 g/L). The peripheral blood smear shows the same features as β^0-thalassemia, including anisocytosis, hypochromia, target cells, basophilic stippling, and nucleated RBCs.

β-Thalassemia Minor (β-Thalassemia Trait). Patients with β-thalassemia minor are very often asymptomatic except at times of hematopoietic stress, such as infections or pregnancy, when they may require, in extreme situations, blood transfusions because of the development of anemia. The CBC on patients with β-thalassemia trait shows low normal or decreased Hb level and hematocrit, decreased MCV (<72 fL) and MCH (<27 pg), and normal RDW. The discriminant factor is <60 pg. However, for patients with liver disease and β-thalassemia, the MCV and MCH may be in the low end of the reference interval.

The peripheral blood smear shows microcytic RBCs with occasional hypochromia, poikilocytosis, and target cells.

The diagnosis of β-thalassemia minor, with appropriate indices in the CBC, is dependent on the finding of a raised Hb A_2 concentration (>3.5%). Iron deplete individuals should become iron replete before a definitive diagnosis of β-thalassemia is made as the Hb A_2 may be falsely low.[109] HPLC is the preferred method for this quantification since densitometric scanning of the Hb A_2 band on an alkaline electrophoresis gel is not recommended because of poor precision and accuracy. In 30% to 40% of all cases of β-thalassemia minor, the Hb F will also be raised (>1.0%). The lifespan of the RBC may be reduced, and diabetics may show a lower Hb A_{1c} compared with normal individuals with equivalent glycemic control. The β-thalassemia mutation may be identified either by Southern blot using mutation specific probes or by gap-PCR.

δβ-Thalassemia. Deletion of both δ- and β-genes results in δβ-thalassemia. Both heterozygous and homozygous conditions have been described. It is found in a variety of ethnic groups but is most prevalent in countries of the Eastern Mediterranean, especially Greece and Italy, and is the result of one of eight mutations that have been described to date. CBC analysis shows a reduced level of Hb (80 to 135 g/L) with low normal or marginally reduced MCV and MCH. HPLC analysis shows an Hb A peak with a reduced Hb A_2 concentration and raised Hb F concentration.

The exception to the preceding description is the Sardinian type of δβ-thalassemia in which there are thalassemic indices on the CBC (low MCV and MCH, normal RDW) with a normal Hb A_2 concentration and an Hb F concentration between 15% and 20%. Hb Lepore is sometimes classified as a δβ-thalassemia because of a reduction in the production of both δ- and β-globin chains or as an Hb variant because of the presence of an abnormal globin chain.

Hereditary Persistence of Fetal Hemoglobin (HPFH). The term hereditary persistence of Hb F is used to describe a group of genetic conditions in which the concentration of Hb F is increased above the upper limit of the reference interval because of the reduction of β-globin synthesis and a compensatory increase in δ-globin synthesis. Two major classes, heterocellular and deletional, of HPFH have been described. Several deletional variants of HPFH have been described, including Greek, Indian, Italian, Corfu, and black.

In black HPFH the Hb F is raised to between 10% and 36% of the total Hb with normal Hb A_2 concentrations. The Hb, MCV, and MCH are within the reference intervals. It is clinically innocuous and asymptomatic. Similarly, there are no clinical abnormalities associated with Greek HPFH although the concentration of Hb F is in the range of 15% to 25%.

Nondeletional HPFH, sometimes named heterocellular HPFH, describes a group of presentations in which the increase of Hb F is distributed heterogeneously among the red cells in otherwise normal individuals. The Hb F concentration varies between 1% and 13% of the total Hb heterozygotes and 19% to 21% in homozygotes. There are no clinical or hematological abnormalities.

Hemoglobinopathies

Although more than 900 hemoglobinopathies have been described, only 9 have some clinical significance. Recent immigration from regions with a high frequency of hemoglobinopathies (South East Asia or Africa) to regions (Western Europe, Central and South America, and Canada) that had low frequencies has increased the incidence of hemoglobinopathies in these areas. The incidental and fortuitous finding of a hemoglobinopathy in the HPLC analysis for the quantification of Hb A_{1c} has increased both the number and incidence of Hb variants.* Several Hb variants (e.g., Hb Rambam, Niigata, and Camden) interfere with HPLC methods for quantifying Hb A_{1c}.

Nomenclature

Hb variants are named using letters (Hbs S, D, E, etc.), the family name of the index case (Hb Lepore), the place of discovery of the variant or place of origin of the propositus (Hb Edmonton) or the name of the river (Hb Saale)[21] flowing through the city in which the propositus lived. In some cases both a letter and name are used as in Hb J-Baltimore, indicating the Hb is classified as having electrophoretic mobility similar to other J Hbs but differs from them in amino acid sequence and was originally discovered in Baltimore. The term AS trait (sometimes abbreviated to S trait) is used to describe a heterozygous state in which one of the β-globin chains is S and the other is A. In instances in which no normal β-globin chain is present (e.g., Hb SD) the β-globin chain present in the higher concentration is usually, although not always, placed first. A systematic nomenclature system is now used alongside the variant name to describe the affected chain and location on the chain and the amino acid substitution. For example, Hb Spanish Town ($\alpha 27(B8)^{Glu \rightarrow Val}$), a Hb variant named after a district in Kingston, Jamaica and found in Jamaicans of African descent, results from a substitution of valine for glutamic acid in position 27 of the α-globin chain, which is located in position 8 of the B helix of the α-chain.

Classification of Hemoglobin Variants

Hb variants are classified according to the type of mutation. Single point mutations in α-globin chain give rise to a substitution of one amino acid residue. As an example Hb San Diego ($\beta 109(G11)^{Val \rightarrow Met}$) has a methionine residue instead of the normal valine at position 109 of the β-chain. Hemoglobin C Harlem ($\beta 6(A3)^{Glu \rightarrow Val}$;$\beta 73(E17)^{Asp \rightarrow Asn}$) is an example of an Hb variant in which two amino acid residues are substituted, namely valine replacing glutamic acid at position 6 and asparagine replacing aspartic acid at position 73 of the β-chain. Hemoglobin C Harlem is electrophoretically similar to Hb C but behaves like Hb S in every other aspect including clinical manifestation. *Deletion* Hb variants arise from the deletion of one to five amino acid residues in the globin chain. Hb Vicksburg ($\beta 75(E19)^{Leu \rightarrow 0}$) is an example in this category of Hb having a deletion of leucine in position 75 of the β-chain. *Insertion* Hbs arise from an insertion of one to three amino acid residues into the globin chain. Hemoglobin Grady is an example in this category having an insertion of a three amino acid residue sequence (glutamine-phenylalanine-threonine) between positions 118 and 119 of the α-chain. *Deletion-insertion* Hbs arise from the deletion of a portion of the normal amino acid residue sequence and the insertion of another sequence with resultant lengthening or shortening of the globin chain. An example of this type of Hb variant is Hb Montreal in which the three normal amino acid residues between positions 72 and 76 of the β-globin chain are replaced with a four amino acid residue sequence. *Elongation* Hbs result from a single base pair mutation or frameshift at the 3′ end of exon 3 or the 5′ end of exon 1 of the α_2- or the β-globin chain. The elongation hemoglobin, Hb Constant Spring (named after an ethnic Chinese family from the Constant Spring district of Jamaica), has an additional 31 amino acid residues joined at position 142 (the carboxy terminal) of the α-chain. *Fusion* Hbs result from the fusion of either an α- or β-globin chain with a portion of another globin chain. Hemoglobin Lepore-Hollandia results from the fusion of the first 22 amino acid residues of the δ-chain, with the amino acid sequence from position 50 onward of normal β-globin. For the latter four categories, the systematic name is long and cumbersome, prompting the universal use of the variant name rather than the systematic nomenclature.

Types of Hemoglobin Variants

In α-chain variants, the variant usually forms less than 25% of the total Hb since the mutation typically occurs only in one of the four genes that code for the α-globin chain. For β-chain variants in the heterozygous state, the variant forms greater than 25% but less than 50% of the total Hb. Based on the mutation of only one of the β-globin chain genes, the β-chain variant should form 50% of the total Hb. However, the formation of Hb A is favored in almost all cases over the variant Hb. This information can be used to categorize an unknown Hb variant as either an α- or β-globin chain variant.

Hb VarDatabase is a relational database of Hb variants and thalassemia mutations and may be accessed at the web site http://globin.cse.psu.edu/hbvar/menu.html.

Hemoglobin S ($b6(A3)^{Glu/Æ Val}$). Hb S, either in the heterozygous or homozygous state, is the most widespread of the Hb variants and arises from a substitution of valine for glutamic acid at position 6 in the A helix of the β-globin chain. Hb S is found in high frequency in West and North Africa, the Middle East (especially Saudi Arabia), and the Indian subcontinent. Approximately 8% of African-Americans are heterozygous for Hb S, and homozygous Hb S is found in 1 in 500 newborns in this group. Four haplotypes originating from different geographic locations have been described. The widespread distribution of the single point gene mutation responsible for the synthesis of Hb S in areas where *P. falciparum* malaria is endemic is due to the protection of Hb S heterozygotes from the worst manifestations of the malaria.

Homozygous Hemoglobin S (HbSS). In homozygous Hb S, a valine for glutamic acid substitution occurs on both β-globin chains because of the inheritance of mutated β-globin chain genes from both parents. The condition is described as "sickle cell anemia or sickle cell disease" because of the sickle shaped RBCs that occur when there is a "sickle cell crisis" and is sometimes written as $\beta^S\beta^S$.[154a]

HPLC analysis (Figure 31-12, *e*) of a hemolysate of an individual homozygous for Hb S shows no Hb A peak with a small Hb A_2 peak. The apparent Hb A_2 concentration may be falsely increased because of the presence of glycated Hb S. Hemoglobin S forms 85% to 90% of the total Hb. The Hb F concentration is variable, with females having higher con-

centrations than men and is somewhat, although not exclusively, haplotype dependent. The highest Hb F concentrations (10% to 25%) are found in individuals from the Middle East and the Indian subcontinent with the Arab-Indian haplotype. Low Hb F concentrations (5% to 6%) are found in the West African Cameroon (sometimes called Senegal) haplotype. The remaining haplotypes, the Benin and Bantu, have Hb F concentrations in the range of 6% to 7%. Increased concentrations of Hb F mitigate to some extent the clinical manifestations of sickle cell anemia. Electrophoresis (Figure 31-10) at both alkaline and acid pH shows a single large band in the Hb S position with small bands at the Hb A_2 and Hb F positions. The sickle cell screen test is positive.

CBC analysis of an individual homozygous for Hb S indicates a moderate to a major decreased Hb level (60 to 100 g/L) with a normal to increased MCV and MCH. In individuals with a concurrent thalassemia, the Hb is further decreased and both the MCV and MCH are lowered. In the neonate the peripheral blood smear shows the occasional sickle and target cells and Howell-Jolly bodies. As a patient's age increases, these features of hyposplenism become increasingly evident. In the adult the percentage of sickle cells observed can be as much as 30% to 40%. In the setting of a sickle cell crisis, fewer sickle cells may be present than when the individuals are clinically well. Howell-Jolly bodies, target cells, Pappenheimer bodies, boat-shaped cells, and nucleated RBCs are noted. The platelet count and neutrophil counts are elevated. Sometimes blister cells in which the Hb appears to be present in only one half of the cell is observed.

Heterozygous Hemoglobin S (HbS Trait). HPLC analysis (Figure 31-12, *f*) of a hemolysate of a blood sample from an individual who is heterozygous for Hb S shows peaks in the Hb A and S positions, with 40% of the total Hb found in the Hb S peak. Hb S concentrations <30% are suggestive of a co-inheritance of α-thalassemia. Hb F concentration is variable. Electrophoresis (Figure 31-10) at both alkaline and acid pH shows bands in the A and S positions

CBC analysis from an individual who is heterozygous for Hb S shows a slightly decreased level of Hb, and typically sickle cells are not seen on the peripheral blood film. Patients are often asymptomatic, and the first time an individual is diagnosed as heterozygous for Hb S (sickle cell trait) is often when an Hb A_{1c} analysis is requested on the individual or when a family study is initiated for genetic counseling. In the United States there are neonatal screening programs designed specifically to detect both heterozygous and homozygous Hb S in newborns. Although individuals with sickle cell trait are clinically asymptomatic, genetic counseling should be considered because co-inheritance of two β-globin gene abnormalities may contribute to a sickle cell disorder. Both α- and β-thalassemia can be co-inherited with heterozygous Hb S.

Hemoglobin SC (Hb SC Disease). SC disease arises when both β-globin chains are substituted at position 6 with either valine (Hb S) or lysine (Hb C). On HPLC analysis peaks are noted in the S and C positions, with the S peak forming the majority of the Hb present.

Electrophoresis (Figure 31-10) at both alkaline and acid pH shows bands in the S and C positions, and the sickling test is positive.

Hemoglobin SD. Hb S may be coinherited with Hb D (SD disease). Individuals with this disease have similar but milder clinical presentation when compared with that of sickle cell disease (Hb SS). HPLC analysis shows two peaks, one in the Hb S position forming approximately 38% to 42% of the total Hb and the other in the Hb D position forming 43% to 45% of the total Hb. The Hb F concentration is usually within the reference interval although concentrations as high as 14% have been observed in some individuals with SD disease. Alkaline electrophoresis shows a band in the S position. Acid electrophoresis shows bands in the S and A positions. The sickling test is positive. CBC analysis shows a greatly decreased level of Hb with normal to slightly elevated MCV. Target, boat-shaped, nucleated, red, and sickle cells—together with anisocytosis and poikilocytosis—are noted on the peripheral blood smear.

Hemoglobin S/O Arab. Co-inheritance of Hb S and Hb O Arab presents a similar or somewhat milder clinical presentation to sickle cell disease and is found in the Middle East and North Africa.

One or more abnormal α-globin chains can combine with Hb S. In African-Americans and West Africans the combination of Hb G Philadelphia ($\alpha 68(E17)^{Asn \rightarrow Lys}$) with Hb S is prevalent. HPLC analysis (Figure 31-12, *i*) on blood samples from these individuals shows at least two major peaks and two smaller peaks. The two major peaks are due to the combination of the normal α-chain with the normal β-chain and the abnormal α-chain with the normal β-chain. The two smaller peaks are due to the combination of the normal α-chain with the abnormal β-chain and the abnormal α-chain with the abnormal β-chain. Electrophoresis at alkaline pH shows major bands in the A and S positions with a minor band in the C position. At acid pH, bands are seen in the A and S positions. CBC analysis gives a slightly decreased Hb level with normal MCV and MCH. α- or β-thalassemia can be co-inherited with Hb G Philadelphia and Hb S. In these cases, CBC analysis results in markedly decreased MCV and MCH with reduced Hb concentration.

Hemoglobin C ($b6(A3)^{Glu \rightarrow Lys}$). Hb C arises from a substitution of lysine for glutamic acid at position 6 of the β-globin chain. Hb C may be found in the homozygous (Hb C disease, $\beta^C\beta^C$) or heterozygous (Hb C trait) states. Hb C is commonly found in West Africa and the Caribbean. It is the second most commonly studied, after Hb S, of all Hb variants. HPLC analysis (Figure 31-12, *g*) on samples from individuals with homozygous Hb C shows a large peak in the C position, with Hb C forming 90% to 95% of the total Hb. Hb F concentrations are variable. Glycated Hb C is found as a small peak eluting before the Hb C peak. The ratio of the

elution times of glycated Hb C to Hb C is the same as that of Hb A_{1c} and Hb A. Electrophoresis at alkaline and acid pH shows a single band in the C position.

Mild to moderate anemia is the most common clinical presentation. CBC analysis shows normal or slightly decreased Hb levels with a normochromic and normocytic red cell morphology. An increase in polychromasia may be present, and the reticulocytes may contribute to an increase in the MCV. The peripheral blood smear shows numerous target cells with occasional nucleated RBCs and characteristic irregular contracted red cells (sometimes called pyknocytes). Hb C crystals may be seen, and bilirubin concentrations may be slightly elevated. Red cell survival and osmotic fragility are decreased.

Heterozygous Hemoglobin C (Hb C Trait). HPLC analysis (Figure 31-12, *h*) and electrophoresis at both alkaline and acid pH (Figure 31-10) on blood samples from individuals who are heterozygous for Hb C show bands in the A and C positions with Hb C forming 30% to 40% of the total Hb. CBC analysis may show target cells and is generally normochromic with the MCV near the lower limit of the reference interval.

Heterozygous Hb C individuals are usually asymptomatic. Genetic counseling may be useful where prospective parents have abnormalities in the β-globin gene.

Hb C may be co-inherited with both α- and β-thalassemia, and the concentration of Hb C is related to the number of functioning α-genes. With only two functioning α-genes, the Hb C concentration can fall to 32% of the total Hb. Co-inheritance of Hb C with either β^0- or β^+-thalassemia results in moderately severe anemia with splenomegaly. The Hb F concentration is increased.

Hemoglobin D Punjab (b121(GH4)$^{Glu\rightarrow Gln}$). Hb D Punjab is an Hb variant in which glutamic acid at position 121 of the β-globin chain is replaced with glutamine. The names Hb D Los Angeles or Hb D Punjab are used to describe this variant, with the former name used more in North America and the latter in the United Kingdom. Hb D Punjab is found in the Punjab region of the Indian subcontinent especially in Sikhs of the Lycus Valley. Large scale immigration from this area to the United Kingdom, the United States and Canada has widened the distribution of Hb D Punjab. Hb D Punjab is also found in Caucasians whose foreparents lived in the Indian subcontinent in the time of the British Raj. Hemoglobin D Punjab is found in the heterozygous (Hb D Punjab trait) and homozygous (Hb D Punjab disease, $\beta^D\beta^D$) states.

HPLC analysis of blood from an individual with homozygous Hb D Punjab shows normal or marginally raised Hb F and Hb A_2 peaks with a large peak in the Hb D position forming >90% of the total Hb. Electrophoresis at alkaline pH shows a band in the S position, which migrates to the A position in acid electrophoresis. CBC analysis shows a mild decrease in Hb levels, MCV, and MCH with target cells observed in the blood smear. Patients present clinically with mild anemia.

HPLC analysis on individuals with Hb D Punjab trait shows two peaks, one at the A position and the other at the D position, with Hb D forming 30% to 40% of the total Hb. The Hb F and Hb A_2 concentrations are within or slightly above the reference intervals. Electrophoresis at alkaline pH shows two bands, one in the A position and the other in the S position. On electrophoresis at acid pH, a single band in the A position is noted. HPLC is the preferred method for identification of Hb D, because a similar electrophoretic pattern, on both alkaline and acid pH, is seen with Hb G. CBC analysis is unremarkable except for the presence of target cells on the blood smear.

Individuals with Hb D Punjab trait are clinically asymptomatic.

Co-inheritance of Hb D Punjab (both heterozygous and homozygous states) with β-thalassemia is common. CBC analysis on these patients shows decreased levels of Hb with markedly decreased MCV and MCH. Target and irregular contracted cells together with hypochromia and anisocytosis are seen on the blood smear. The quantification of Hb A_2 in individuals with coinheritance of Hb D Punjab and β-thalassemia presents a challenge to the laboratory since HPLC analysis underestimates the Hb A_2 concentration because of an unstable rising baseline in these individuals. Although not normally recommended, quantification of Hb A_2 by densitometry on alkaline electrophoresis may be the only method available to many laboratories. CBC analysis shows a greatly decreased level of Hb with low MCV and MCH. The blood smear shows target and contracted cells with hypochromia and anisocytosis.

Individuals with coinheritance of Hb D Punjab and β-thalassemia present with a notable compensated anemia.

Hemoglobin D Iran (b22(B4)$^{Glu\rightarrow Gln}$). Hb D Iran is a β-globin chain variant in which glutamine replaces glutamic acid at position 22 of the β-globin chain.

On HPLC analysis peaks are seen in the A and A_2 positions with the quantification for HbA_2 far above that normally expected. Alkaline electrophoresis shows two bands, one in the A position and the other in the S position. On acid electrophoresis a single band in the A position is noted.

Individuals with Hb D Iran are asymptomatic.

Hemoglobin E (b26(B8)$^{Glu\rightarrow Lys}$). Hb E is a β-chain variant with lysine replacing glutamic acid at position 26 of the β-globin chain. More individuals have the Hb variant Hb E than any other variant. Hb E is found in both the homozygous and heterozygous states and combined with β-thalassemia. It is widespread in the Far East including Southern China, Cambodia, Thailand, and Laos. Hb E is increasingly found in the United States and Canada caused by immigration from this area.

HPLC analysis of blood from individuals with homozygous Hb E (Hb E disease, $\beta^E\beta^E$) shows a single peak (>90% of the total Hb) co-eluting with Hb A_2. Hemoglobin F is within or marginally above the reference interval. On alkaline electrophoresis a single band is noted in the C position, which migrates to the A position in acid electrophoresis.

CBC analysis shows normal to marginally decreased Hb levels with low MCV and MCH. Target cells are noted in the peripheral blood smear. Iron studies are normal.

Homozygous Hb E individuals are usually asymptomatic although slight anemia may be present.

HPLC analysis of blood from individuals with heterozygous Hb E shows two peaks, one in the A position and the other in the A_2 position. Hb E forms approximately 30% of the total Hb. CBC analysis shows normal Hb levels and occasionally low MCV. Target cells are noted in the peripheral blood smear. Iron studies are normal.

Heterozygous Hb E individuals are usually asymptomatic although slight anemia may be present.

The co-inheritance of Hb E and thalassemia produces an anemia of variable severity. The HPLC on a patient with co-inheritance of β-thalassemia and homozygous E is shown in Figure 31-12, *c*. Co-inheritance of homozygous Hb E and β-thalassemia leads to a severe anemia with greatly reduced Hb levels, MCV, and MCH with increased Hb F concentration. Numerous target cells are noted on the peripheral blood smear together with microcytosis, anisocytosis, hypochromia, and a few nucleated red cells. Iron studies are normal. In the most severe cases, the clinical presentation is similar to that of β^0-thalassemia, and transfusion may be the only therapy. Co-inheritance of heterozygous Hb E with α-thalassemia produces a less severe anemia with low Hb and MCV and MCH. Target cells are noted on the peripheral blood smear together with microcytosis and hypochromia. Patients who are pregnant may need to be monitored closely although transfusion is not usually required.

The quantification of Hb A_2, which is important in the diagnosis of possible coinheritance of β-thalassemia with Hb E, provides a challenge to the laboratory since Hb E and Hb A_2 co-elute. Molecular studies are the only satisfactory method to establish coinheritance of Hb E and β-thalassemia, although the severity of the disease, family studies, and an increased Hb F may lead to a suspicion of coinheritance.

Hemoglobin O Arab (b121(GH4)$^{Glu\rightarrow Lys}$). Hb O Arab is a β-chain variant with lysine replacing glutamic acid at position 121 of the β-globin chain. Hb O Arab is found in a wide variety of ethnic groups in North Africa and Eastern Europe and is not confined, nor is it even common, among Arab populations. Hb O Arab has been found in both the heterozygous and homozygous states.

HPLC analysis of blood from an individual with homozygous Hb O Arab shows a single band between the S and C positions, with Hb O Arab forming >90% of the total Hb. Electrophoresis at alkaline pH shows a band close to the C position. On electrophoresis at acid pH, a band between the A and S positions (but closer to A) is seen. CBC analysis shows a normal or marginally low Hb level, MCV, and MCH. The peripheral blood smear shows slight microcytosis.

There are no unusual hematological features on individuals with heterozygous Hb O Arab. HPLC analysis on blood from these individuals shows two peaks, one in the A position and the other eluting close to the C position and forming 30% to 40% of the total Hb. Electrophoresis at alkaline electrophoresis shows bands in the A and close to the C position. On acid electrophoresis, two bands are noted: one in the A position and the other in a position between the A and S positions.

Hybrid Hemoglobins. Hybrid Hbs, or crossover Hbs, describe a group of Hb variants in which one of the globin chains is a hybrid of amino acid sequences of two other globin chains. The term crossover Hb is sometimes used because there is a point in the amino acid sequence in which there is a crossover from the amino acid sequence of one globin chain to another globin chain. Individuals with these hybrid Hb variants present with the clinical features and laboratory findings, particularly in their CBC, that are similar to thalassemia. The production of the hybrid globin chain is reduced. Hb Lepore is the prototypical hybrid Hb.

Hemoglobin Lepore. Hb Lepore is classified as a δβ-hybrid Hb variant on the basis that the non–α-chain is a hybrid of δ- and β-globin chains. It is unique in that it is the only hemoglobinopathy named after the family name of the index case. Delta-beta hybrid Hbs arise because there are deletions of part of the 3′ portion of the δ-globin gene and in the 5′ portion of the β-globin chain with a resultant formation of a δβ-fusion gene. Three distinct variations of Hb Lepore have been described. In Hb Lepore-Hollandia (δβ-hybrid [δ through 22; β from 50]), a variant found in Canada and Papua New Guinea, there is fusion of the first 22 amino acid residues of the δ-globin chain with the amino acids from position 50 onwards of the β-globin chain. In Hb Lepore-Baltimore (δβ-hybrid [δ through 50: β from 86]), found mainly in individuals of Spanish ancestry, the first 50 amino acid residues of the δ-globin chain are fused with the amino acid residues from position 86 of the β-globin chain. In Hb Lepore-Boston-Washington (δβ-hybrid [δ through 87; β from 116]), the most common Hb Lepore, the first 87 amino acid residues of the δ-globin chain are fused with the amino acid residues from position 116 onwards of the β-globin chain. Hb Lepore-Boston-Washington, sometimes called Hb Lepore-Boston, is found mainly in individuals of Italian descent although it has been found in individuals from Eastern Europe.

HPLC analysis of blood from individuals with Hb Lepore shows a greatly raised Hb A_2 level with a marginally reduced Hb A concentration. The Hb A_2 concentration is usually greater than 10% of the total Hb and is falsely increased because of the co-elution of Hb A_2 and Hb Lepore. Electrophoresis at alkaline pH shows a band in the S position for Hb Lepore-Boston-Washington and in a position between the A and S positions for the other Hb Lepore variants. At acid pH there is a single band in the A position for all Hb Lepore variants.

CBC analysis shows a greatly reduced level of Hb, MCV, and MCH for homozygotes for Hb Lepore. The hematolog-

ical findings are very similar to β-thalassemia major or intermedia. CBC analysis on heterozygotes shows a slightly reduced MCV and MCH. The hematology findings are very similar to β-thalassemia trait. Iron studies are normal in both heterozygotes and homozygotes. The similarity of the hematology in Hb Lepore and β-thalassemia makes the careful review of the HPLC and electrophoretic analysis essential to distinguish the two. The two key pieces of evidence to distinguish between the two are the finding of a greatly raised Hb A_2 on HPLC analysis and a small band in the S position on electrophoresis at alkaline pH.

Elongation Hemoglobins. Elongation Hbs, of which there are 13, include seven α-chain and six β-chain variants, result from the lengthening of either the C or N terminus of either globin chain. The most important, from a clinical perspective, are the five C terminal α-chain variants in which the terminal codon TAA is changed and there is an addition of an amino acid sequence. The prototypical elongation Hb is Hb Constant Spring. In this variant the C terminal TAA codon is changed to CAA in the α_2-gene and there is an addition of a 31 amino acid sequence at the C terminal end to give an α-globin chain length of 173 amino acid residues rather than the normal 142 residue length. This increase in the length results in instability of the Hb variant, and synthesis of this elongated globin chain is reduced. Hemoglobin Constant Spring is found in South East Asia especially in Vietnam, Cambodia, and Laos and is found in both the heterozygous and homozygous states.

Patients with Hb Constant Spring present with slightly reduced Hb, MCV, and MCH with hypochromia and microcytosis in the peripheral blood smear. Iron studies are often normal.

The instability of Hb Constant Spring presents a challenge to the laboratory diagnosis of this variant. The blood used for analytical procedures should be as fresh as possible, and samples greater than 24 hours old should not be used. HPLC analysis of blood from individuals with Hb Constant Spring shows a small peak in the C position, which forms approximately 4% to 6% of the total Hb in the homozygote and 1% to 3% in the heterozygote. On electrophoresis at alkaline pH, a small band migrating cathodally to the application point may be seen. This electrophoretic mobility is unique in that it is the only Hb variant that moves toward the cathode rather than the anode.

Hemoglobin Constant Spring is commonly found in combination with α^0-thalassemia especially the $-^{SEA}$ mutation. The clinical presentation of this combination results in a severe form of Hb H disease.

IRON

Normally, very small quantities of iron are present in most cells of the body, in plasma, and in other extracellular fluids, and the body rigorously conserves its iron supply, so that less than 0.1% of the body iron content is lost daily, mostly in desquamated cells.

BIOCHEMISTRY

Distribution

Body iron is distributed into a number of different compartments that include Hb, storage iron, tissue iron, myoglobin, and a labile pool. The average amount of iron in these compartments is summarized in Table 31-1.

Hemoglobin

One mL of erythrocytes contains 1 mg of iron. In a 70-kg male the red cell mass is about 2 L, therefore it contains about 2 g of Hb iron.[10]

Storage Iron

Iron is stored in the body in the form of ferritin and hemosiderin.

Ferritin. Ferritin consists of a protein shell surrounding an iron core,[23,76] and hemosiderin is formed when ferritin is broken down in secondary lysosomes.[6,180] Hemosiderin therefore appears to represent the end point of the intracellular storage iron pathway. Ferritin consists of an apoferritin shell and an interior ferric oxyhydroxide $(FeOOH)_x$ crystalline core. The apoferritin shell is composed of 24 subunits, which are either L (light) or H (heavy) ferritin chains. The proportion of light chains to heavy chains differs from tissue to tissue (Figure 31-18). The shell is 12 to 13 nm in diameter, and its interior cavity is 7 to 8 nm in diameter. Only ferrous iron is taken up by ferritin, and it is oxidized by a catalytic site on the H chain. The H chains contain small intrasubunit channels, which may be used by iron entering the cavity. The exact composition of the FeOOH core crystal is somewhat different in different species and contains different amounts of phosphates. In humans it is a ferrihydrite ($5\ Fe_2O_3 \cdot 9\ H_2O$). Release of iron from ferritin is probably nonenzymatic and may involve reduction by reduced flavin mononucleotide or other reducing substances. The resultant Fe^{2+} leaves the crystal and diffuses out through a pore of the ferritin shell.

TABLE 31-1 Average Iron Content of Compartments in an Average 70-kg Male (Based on Estimates)

Compartment	Iron Content (mg)	Total Body Iron (%)
Hb iron	2000	67
Storage iron (ferritin, hemosiderin)	1000	27
Myoglobin iron	130	3.5
Labile pool	80	2.2
Other tissue iron	8	0.2
Transport iron	3	0.08

From Fairbanks VF, Beutler E. Iron metabolism. In: Beutler E, Lichtman MA, Coller BS, Kipps TJ, Seligsohn U, eds. Williams hematology. New York: McGraw-Hill, 2001:295-304.

Ferritin is found in nearly all cells of the body. In hepatocytes of the liver and in the macrophages of the marrow and other organs, ferritin provides a reserve of iron readily available for formation of Hb and other heme proteins, in a form in which the iron is shielded from body fluids, so that it is unable to produce oxidative damage, as would be the case if it were in ionic form. In men the total body content of stored iron, mostly as ferritin, is approximately 800 mg; in healthy women, it ranges up to 200 mg. Minute quantities of ferritin are also present in serum in concentrations proportional to total body stored iron. This ferritin differs from tissue ferritin in that it is glycosylated, contains mostly L chains, and is poor in iron, representing mostly apoferritin. Liver injury and a large number of pathological processes result in release of relatively large amounts of ferritin into plasma.

Hemosiderin. *Hemosiderin* is aggregated, partially deproteinized ferritin. In contrast to ferritin, hemosiderin is insoluble in aqueous solutions, a difference that has traditionally been used to distinguish these two iron storage compounds. Iron is only slowly released from hemosiderin, possibly because it occurs in relatively large aggregates and therefore has a much smaller surface/volume ratio. Like ferritin, hemosiderin normally is found predominantly in cells of the liver, spleen, and bone marrow.

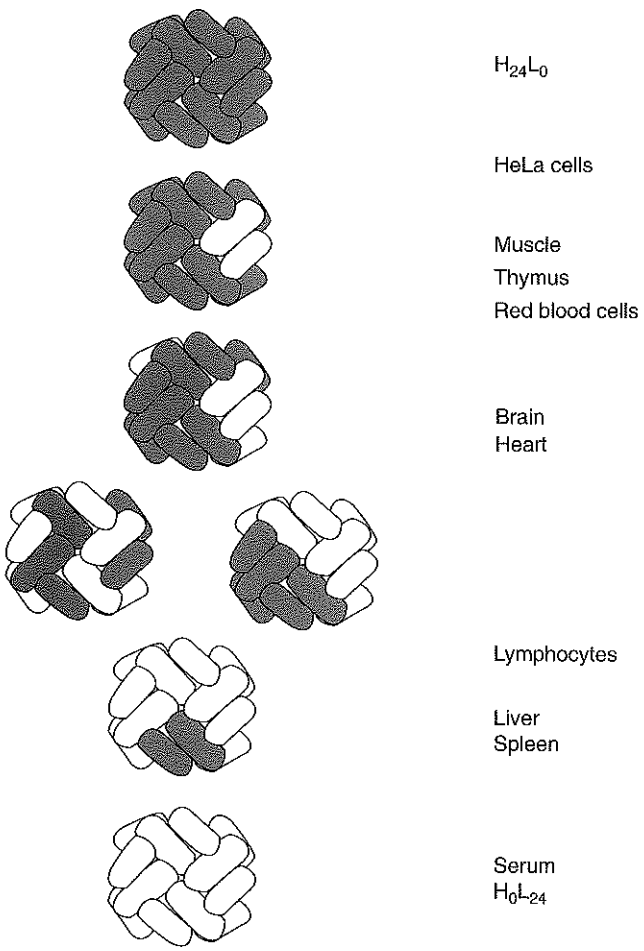

Figure 31-18 Schematic representation of the subunit structure of ferritins from various tissues. *(From Harrison PM, Arosio P. The ferritins: molecular properties, iron storage function and cellular regulation. Biochim Biophys Acta 1996;1275:161-203.)*

Tissue Iron

Numerous cellular enzymes and coenzymes require iron, either as an integral part of the molecule or as a cofactor. Notable are the *peroxidases* and *cytochromes*, all of which, like Hb, are heme proteins. Other enzymes, such as *aconitase* and *ferredoxin*, have iron that is coordinated with sulfur in a so-called iron-sulfur cluster. Nearly half of the enzymes of the *Krebs cycle* contain iron. These enzymes and coenzymes, which appear in all nucleated cells of the body, are referred to collectively as the *tissue iron compartment*. The tissue iron compartment normally amounts to approximately 8 mg. Although a small compartment, it is metabolically critical. Some iron enzyme activities diminish early in the course of iron deficiency.[58]

Myoglobin

Myoglobin very closely resembles a single Hb subunit. Because myoglobin does not form tetramers, it lacks the allosteric properties of Hb.

Labile Pool

Approximately 80 mg of iron is found in the labile pool. This compartment has no clear anatomical location; rather it is a concept derived from kinetic measurements with radiolabeled iron.[94]

Transport

Iron is transported from one organ to another by a plasma iron transport protein, *apotransferrin*. This β_1-globulin with a molecular weight of 75,000 Da has two iron binding sites per molecule. Each of these sites may bind one Fe^{3+} ion together with one ion of HCO_3^-. The apotransferrin-Fe^{3+} complex is called *transferrin*. Normally, there is a total of approximately 2.5 mg of iron in plasma. Particularly under abnormal conditions, such as in patients with thalassemia, a small amount of iron that is not bound to apotransferrin is found in the plasma.[28,80] When transferrin binds to the *transferrin receptor* of cells the transferrin-receptor complex is internalized into a vacuole that becomes acidified, releasing the iron from transferrin. The apotransferrin is then transported back to the cell surface, ready to transport another transferrin molecule to the interior of the cell. This series of reactions has been designated *the transferrin cycle*. The transferrin receptor forms a complex with the HFE protein, producing minor kinetic changes in transferrin binding.[106,134] The significance of this association in the regulation of iron homeostasis is not fully understood.

Regulation of Iron Homeostasis

The amount of iron loss from the body depends only minimally upon the iron burden; regulation of body iron content

is therefore achieved almost entirely by modulating the amount of iron absorbed from the upper intestinal tract.

Normal Iron Balance

The average American diet provides 10 to 15 mg of iron daily, mostly in the form of the heme proteins, Hb, and myoglobin, in meat. In the past, a significant component of iron in the diet consisted of inorganic iron leached from iron utensils. Normally, approximately 1 mg of iron is absorbed each day. Absorption occurs principally in the duodenum. Heme is absorbed directly as such. To be absorbed, inorganic iron must be in the ferrous state (Fe^{2+}).

Proteins That Affect Iron Homeostasis

In spite of extensive research efforts, the mechanism by which the body normally regulates its iron content remains a mystery. However, a considerable number of proteins that appear to play a role in iron homeostasis have been discovered; mutations of these proteins in humans and/or their targeted disruption or overproduction in mice can be shown to result either in iron overload or in iron deficiency. Table 31-2 summarizes the effects of some of these proteins on iron homeostasis. The exact role of each of these proteins is not fully understood, but a widely adopted schema of the participation of some of them in iron transport across the intestinal mucosal cell is illustrated in Figure 31-19.

Analytical Methodology

A number of methods are used to measure iron and related analytes. These include methods for serum iron, iron binding capacity, transferrin saturation, and serum ferritin.

Methods for Serum Iron, Iron Binding Capacity, and Transferrin Saturation[62,90,144]

Principle

With serum iron assays, iron is (1) released from transferrin by decreasing the pH of the serum, (2) reduced from Fe^{3+} to Fe^{2+}, and (3) complexed with a chromogen such as bathophenanthroline or ferrozine. Such iron-chromogen complexes have an extremely high absorbance at the appropriate wavelength, which is proportional to iron concentration.

TABLE 31-2 Proteins That Affect Iron Homeostasis and Man and Mouse

Protein	Effect of Deficiency	References		Comments
		Human Data	Murine Data	
HFE	Increased Fe	59	9,107,188	Most patients with hereditary hemochromatosis are homozygous for the 845 A > G (C282Y) mutation of this gene
β_2-Microglobulin	Increased Fe		49,153	Believed to function by preventing transport of *HFE* to membrane
Transferrin	Increased Fe	2,15	169	
Transferrin receptor-1	Lethal increased CNS Fe	Unknown	107	
Transferrin receptor-2	Increased Fe	33	65	
Ferroportin (SLC11A3)	Increased Fe	66,125,150		Dominant inheritance of iron overload
Hephaestin	Fe deficiency	Unknown	173	Sex-linked gene deletion is cause of *sla* mouse
Nramp1 (SLC11A1)	Alters iron distribution in macrophages	Unknown	186	Deficiency increases susceptibility to infection in mice
Nramp2 (DMT-1)	Fe deficiency	Unknown	63,64	The naturally occurring mutations found in the *mk* mouse and the Belgrade rat are the same
Ceruloplasmin	Fe increased	123	75	Brain accumulation and neurological disease
Hepcidin	Fe increased	151	122,140	

Optical characteristics of bathophenanthroline, of ferrozine, and of alternative chromogens are shown in Table 31-3. The assay may be performed manually or in an automated fashion by any of several commercially available methods.

The serum unsaturated iron binding capacity and total iron binding capacity (TIBC) are determined by addition of sufficient Fe^{3+} to saturate iron binding sites on transferrin. The excess Fe^{3+} is removed (e.g., by adsorption with light magnesium carbonate [$MgCO_3$] powder), and the assay for iron content is then repeated. From this second measurement, the TIBC is obtained. Transferrin saturation is calculated as follows:

$$\text{Transferrin saturation (\%)} = \frac{100 \times \text{serum iron}}{\text{TIBC}}$$

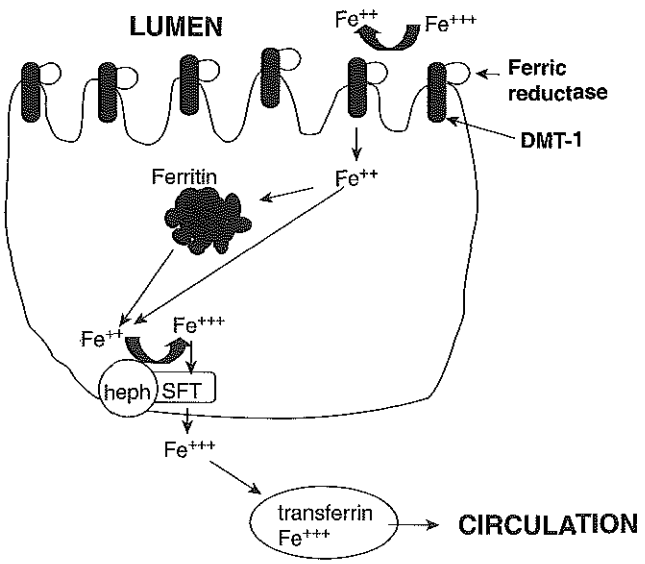

Figure 31-19 Schematic representation of some of the steps that may occur when iron is transported from the intestinal lumen to the blood. *Heph*, Hephaestin; *SFT*, stimulator of iron transport; *DMT-1*, divalent metal transporter-1.

Reference Intervals

Normal reference values differ by as much as 35% between commercial methods. Therefore a generic reference interval can no longer be stated. Many of the commercially available methods appear to underestimate the true value of serum iron concentration by 25% or more, and some appear to be unreliable at concentrations of serum iron less than 30 µg/dL (5 µmol/L). Methods that include deproteinization, either by precipitation or by dialysis, consistently appear to provide results that are substantially higher than those results obtained by methods that do not include a step of deproteinization. From a practical standpoint, if an automated commercial method is used, it is advised that a laboratory independently define its own reference intervals.

Clinical Relevance

The serum iron concentration refers to the Fe^{3+} bound to serum transferrin and does not include the iron contained in serum as free Hb. The serum iron concentration is decreased in many but not all patients with iron deficiency anemia and in chronic inflammatory disorders such as acute infection, immunization, and myocardial infarction (Table 31-4). Serum iron concentration diminishes especially in patients who are beginning to respond to specific hematinic therapy for anemias of other causes such as treatment of pernicious anemia with cyanocobalamin. Acute or recent hemorrhage, including that caused by blood donation, results in low serum iron concentration. Serum iron con-

TABLE 31-3 Characteristics of Some Chromogens Used in Iron Assays

	CHROMOGEN		
Common Name	**Chemical Name**	**Absorbance Maximum of Fe^{2+} Complex (nm)**	**Molar Absorbance of Fe^{2+} Complex**
Bathophenanthroline disulfonate, sodium	4,7-bis(4-phenyl sulfonic acid)-1,10-phenanthroline, sodium salt	534	22.14×10^3
Tripyridyl triazine	2,4,6-tripyridyl-*s*-triazine	593	22.6×10^3
Ferrozine	3-(2-pyridyl)-5,6-bis(4-phenyl sulfonic acid) 1,2,4 triazine, sodium salt	562	28.0×10^3
Terosite	2,6-bis(4-phenyl-2,2-pyridyl)-4-phenyl pyridine	583	30.2×10^3

Modified from Carter P. Spectrophotometric determination of serum iron at the submicrogram level with a new reagent (ferrozine). Anal Biochem 1971;40:450-8.

centration decreases during menstruation. Use of hormonal contraceptives raises serum iron concentration, but on cessation of contraceptive hormone intake, serum iron concentration decreases as much as 30% concurrently with uterine bleeding.

Greater than normal concentrations of serum iron occur in iron loading disorders such as hemochromatosis, in patients with aplastic anemia, in acute iron poisoning in children, and after oral ingestion of iron medication or parenteral iron administration or acute hepatitis. For example, one 0.3-g tablet of ferrous sulfate ingested by an adult may raise the serum iron concentration by 300 to 500 μg/dL (50 to 90 μmol/L).

Because normally only about one third of the iron binding sites of transferrin are occupied by Fe^{3+}, serum transferrin has considerable reserve iron binding capacity. This is called the serum unsaturated iron binding capacity. The TIBC is a measurement of the maximum concentration of iron that transferrin can bind. The serum TIBC varies in disorders of iron metabolism. It is often increased in iron deficiency and decreased in chronic inflammatory disorders or malignancies, and it is often decreased also in hemochromatosis.

Comments and Precautions

1. Except when atomic absorption spectroscopy is used, hemolysis has very little effect on the serum iron assay results because Hb iron is not released from heme by acid treatment. However, when serum specimens show marked hemolysis, a small amount of iron may be liberated from Hb. Such sera should be rejected.
2. Many factors influence serum iron concentration and TIBC. Changes that may be observed in various physiological or pathological conditions are listed in Table 31-4. Day-to-day variation is quite notable in healthy people. A distinct diurnal variation results in serum iron concentrations being lower in the afternoon than morning and quite low in the evening (as low as 10 to 20 μg/dL [2 to 4 μmol/L] in healthy people). Because of the numerous causes of low serum iron concentration, results must be interpreted with caution. Furthermore, many people with mild iron deficiency have normal values for serum iron concentration and TIBC.
3. Because of the great quantities of iron in the environment, scrupulous care is necessary to ensure that glassware, water, and reagents do not become contaminated with iron.

TABLE 31-4 Conditions Known to Affect Serum Iron Concentration, Total Iron Binding Capacity, and Transferrin Saturation

Condition	Effect
Diurnal variation	Normal values in morning; low values in midafternoon; very low values near midnight
Menstrual cycle	Premenstrually, elevated values (SI increased by 10%-30%); at menstruation, low values (SI decreased by 10%-30%)
Pregnancy	May elevate SI owing to increased progesterone; may lower SI owing to iron deficiency
Ingestion of iron (including iron-fortified vitamins)	High values; may raise SI by +54 μmol/L (+300 μg/dL) and Tsat to 100%
Oral contraceptives (progesterone-like)	High values; may raise SI to >36 μmol/L (>200 μg/dL) and Tsat to 75%; also elevates TIBC
Iron contamination of syringe, vacutainer tube, or other glassware (phenomenon may be rare, sporadic, very difficult to prove)	High values; e.g., SI >30 μmol/L (>170 μg/dL); Tsat of 75%-100%
Iron dextran injection	Very high values; SI may be >180 μmol/L (>1000 μg/dL), Tsat 100%, probably from circulating iron dextran; effect may persist for several weeks
Hepatitis	Very high values; SI may be >180 μmol/L (>1000 μg/dL) owing to hyperferritinemia from hepatocyte injury
Acute inflammation (respiratory infection), abscess, immunization, myocardial infarction	Low or normal SI; normal or low Tsat
Chronic inflammation or malignancy	Low or normal SI; normal or low Tsat
Iron deficiency	Low or normal SI; low or normal Tsat; increased TIBC
Iron overload (hemochromatosis)	High SI; high Tsat; normal or low TIBC

From Fairbanks VF. Laboratory testing for iron status. Hosp Pract 1991;26:19.
SI, Serum iron concentration; *TIBC,* total iron binding capacity; *Tsat,* transferrin saturation.

4. Serum transferrin concentration may be estimated from the TIBC by the following relationship:

$$\text{Serum transferrin (g/L)} = 0.007 \times \text{TIBC (}\mu\text{g/dL)}$$

The relationship is not entirely linear because a small portion of iron in serum is bound to other proteins. Therefore the calculated TIBC values are slightly higher than the amount of transferrin-bound iron. These small differences, however, are of no practical consequence. Immunoassays are available for assay of serum transferrin concentration. Results of the immunological measurement of transferrin concentration correlate with those of the TIBC assay. A slight advantage for the immunoassay of transferrin is that the required volume per specimen is much smaller.

Methods for Serum Ferritin

Principle

Serum ferritin assay may be performed by any of several methods, including immunoradiometric assay, ELISA, and immunochemiluminescent and immunofluorometric methods. Reagents for this assay are available in kit form and in automated immunoassay instruments from several manufacturers. The manufacturers' instructions should be followed.

Reference Intervals

Reference intervals for serum ferritin levels are summarized in Table 31-5. However, considerable variation in reference values has been observed with different methods for serum ferritin assay. Consequently, reference intervals must be determined for each laboratory.

Clinical Relevance

Ferritin is present in the blood in very low concentration. Although it is an acute phase protein, under normal conditions it roughly reflects the body iron content. The circulating protein is iron poor and largely consists of iron-poor, glycosylated L chains; it is largely apoferritin. The plasma ferritin concentration declines very early in the development of iron deficiency, long before changes are observed in blood Hb concentration, RBC size, or serum iron concentration. Thus measurement of serum ferritin concentration can serve as a very sensitive indicator of iron deficiency that is uncomplicated by other concurrent disease. Alternatively a large number of chronic diseases result in increased serum ferritin concentration.[142] These diseases include chronic infections; chronic inflammatory disorders, such as rheumatoid arthritis or renal disease; heart disease; and numerous malignancies, especially lymphomas, leukemias, breast cancer, and neuroblastoma. In patients who have any of these chronic disorders together with iron deficiency, serum ferritin concentration is often normal. An increase in plasma ferritin concentration occurs in viral hepatitis or after toxic liver injury as a result of release of ferritin from damaged liver cells. Plasma ferritin concentration is also increased in patients with iron storage disease and is used to gauge the effectiveness of phlebotomy therapy. However, as a screening test for detection of early iron overload, measurement of serum ferritin concentration appears to be less sensitive than measurement of serum iron concentration, TIBC, and percent transferrin saturation.

TABLE 31-5 Reference Intervals for Serum Ferritin

	ng/mL	µg/L
Newborn	25-200	25-200
1 mo	200-600	200-600
2-5 mo	50-200	50-200
6 mo-15 yr	7-140	7-140
Adult man	20-250	20-250
Adult woman	20-200	20-200
Iron overload[182]		
Adult male	>400	>400
Adult female	>200	>200

From Tietz NW, (ed). Clinical guide to laboratory tests, 3rd ed. Philadelphia: WB Saunders Co, 1995.

Comments and Precautions

1. Replicate same-day assays on the same specimen should have a coefficient of variation (CV) of ± 4% for ferritin concentrations of 100 to 300 µg/L and ±10% for ferritin concentrations of 10 to 20 µg/L.
2. Because precision decreases at very high serum ferritin concentration, all specimens with results exceeding 80 µg/L should be diluted with diluting sera to the 200- to 400-µg/L range and repeated. Any specimen with greater than a 7% difference between duplicate assay results should be reassayed.
3. A high-dose hook effect that is similar to a prozone phenomenon formerly complicated interpretation of serum ferritin assays; specimens with actual ferritin concentration exceeding 1000 µg/L could exhibit count rates that would be obtained at normal serum ferritin concentration. Fortunately, currently available reagents no longer result in the hook effect when serum ferritin concentration is high.

Method for Red Cell Volume and Hemoglobin Content

MCV and MCHC are the red cell indices used to characterize the blood of patients with anemia (see Chapter 11). Laser light scattering is used to measure the hemoglobin content and concentration of individual red cells.[120] This is an early indicator of iron deficiency. Its usefulness is limited in patients with MCV values of >100 fL, but in others it compares favorably with other measurements of iron status.[42,54,114,164]

Method for Serum Transferrin Receptor

The cell membranes of the developing RBC precursors in bone marrow are very rich in transferrin receptors, to which the iron-transferrin complex binds before it is internalized

and the iron is released from transferrin in the cytosol. The number of transferrin receptors increases in the presence of iron deficiency and decreases in iron excess. These variations in the quantity of transferrin receptors in erythropoietic tissue are also reflected in changes in serum transferrin receptor, but to a large extent the serum transferrin receptor levels reflect the amount of erythropoietic activity, regardless of the iron status of the patient.

Clinical Significance

Iron deficiency and iron overload are the major disorders of iron metabolism. There are, in addition, many diseases in which abnormal distribution of iron may play primary or secondary roles. Included are such disorders as hyperferritinemia with cataracts,[148] aceruloplasminemia, GRACILE syndrome,[58,60,148] neuroferritinopathy,[46] atransferrinemia, and possibly neurodegenerative disease such as Parkinsonism, Hallervorden-Spatz syndrome, and Alzheimer's disease.[160] These latter disorders will not be discussed further here.

Iron Deficiency

Iron deficiency is one of the most prevalent disorders of humans.[39] It is particularly a disease of children, of young women, and of older people, but it occurs in people of all ages and all social strata. In children it is frequently caused by dietary deficiency, because milk has a low iron content. In adults it is almost always the result of chronic blood loss or childbearing.[58]

Many different measurements have been advocated for the diagnosis of iron deficiency. Originally, emphasis was placed upon the red cell indices; hypochromic anemia was generally considered a synonym for iron deficiency in the first half of the twentieth century. Subsequently the staining of the marrow for iron measurement of the serum iron and the iron binding capacity, serum ferritin, and erythrocyte protoporphyrin became practical, and were used and studied extensively for their ability to diagnose iron deficiency. Circulating transferrin receptor and reticulocyte Hb levels also have been found to have diagnostic value. Of all of these tests, the marrow iron is probably the most reliable but the least practical for any but patients with complex diagnostic problems. However, even it can be misleading (1) when the sample size or observer skill is insufficient,[5] (2) in patients who have been treated with iron by the parenteral route, (3) where stainable iron may be present in the face of deficiency,[128] and (4) in patients with myeloproliferative disease.[40,161]

Although most methods very readily identify severe, uncomplicated iron deficiency, the large number of tests that have been advocated for the diagnosis of iron deficiency is a reflection of the fact that none by itself is sufficient to detect mild iron deficiency or iron deficiency in a clinically complex setting. Receiver operator characteristic curves (ROC) confirm that no one method is superior, and that different studies differ in the conclusions that they draw regarding advantages of one method over another.[61,114,167,172]

Iron Overload

Hemosiderosis, hemochromatosis, and some anemias are conditions associated with iron overload and iron storage diseases.

Hemosiderosis

Hemosiderosis is a term used to imply iron overload without associated tissue injury. It occurs locally in sites of bleeding or inflammation, and may be widespread in persons who have been given large amounts of iron, either as iron medication or as blood transfusions.

Hemochromatosis

Hemochromatosis is a condition in which the body accumulates excess amounts of iron; it is one of the most common genetic diseases in humans. The symptoms of hemochromatosis include the "classic triad" of bronzing of the skin, cirrhosis, and diabetes. Other manifestations include cardiomyopathies and arrhythmias, endocrine deficiencies, and possibly arthropathies.

Secondary hemochromatosis is the consequence of the increased administration and absorption of iron. The administration of iron includes that given with the transfusions that are required in certain anemic patients and the ill-advised and unfortunate administration of iron to anemic patients who are not actually iron deficient. The most common causes of secondary hemochromatosis are thalassemia major and acquired myelodysplastic states, but there are many other circumstances in which secondary iron overload occurs, including pyruvate kinase deficiency and congenital dyserythropoietic anemias.

Hereditary hemochromatosis is the most common hereditary form of hemochromatosis. It results from hereditary abnormalities of proteins that regulate iron hemostasis. In recent years, the genetic lesions responsible for many forms of the disease have been discovered. It is an adult onset disorder, formerly called *primary hemochromatosis* or *idiopathic hemochromatosis,* which is linked to the HLA loci on chromosome 6.

Other forms of hemochromatosis include a severe, early onset form, designated *juvenile hemochromatosis,* and an iron storage disease in which storage takes place largely in macrophages, *African iron overload* and *ferroportin deficiency.* An effort has been made recently to classify hereditary forms of hemochromatosis as types 1 through 5, but this does not serve to clarify our understanding of the disorders and inaccurately groups iron storage disease with different etiologies into the same "type." This classification will therefore not be employed here.

Hereditary Hemochromatosis. Hereditary hemochromatosis is the classical disorder of iron overload.[32] It is due to an inborn error of iron absorption; the precise mechanism remains unknown. Approximately 80% of whites of Northern European origin are homozygotes for a common mutation of the *HFE* gene. This mutation (845 G > A; C282Y) is a common polymorphism in Northern Europe.

Some 10% to 15% of Northern Europeans are heterozygous for this mutation and therefore about 5/1000 are homozygotes. Although it has been shown to associate with the transferrin receptor, the mechanisms by which it causes increased iron absorption are not understood. The biochemical penetrance of the homozygous state for the major (C282Y) mutation is fairly high; more than 50% of such individuals have elevated transferrin saturations and/or ferritin levels[12,13] and about 10% have elevated serum glutamic oxaloacetic transaminases levels. Although some investigators have maintained that many or most homozygotes are seriously affected[32,129] numerous recent studies show that the clinical penetrance of the homozygous state is very low, probably of the order of 1%,[3,13,92,139] and there is no significant effect on lifespan.[174] Rarely, hereditary hemochromatosis results from mutations in the transferrin receptor-2 gene.[149] This type of hemochromatosis is indistinguishable from classical hereditary hemochromatosis caused by a mutation in the *HFE* gene.

Juvenile Hemochromatosis. Juvenile hemochromatosis is a rare disorder that resembles hereditary hemochromatosis clinically, but that has a much earlier average age of onset and a greater tendency to develop endocrine and cardiac manifestations than does hereditary hemochromatosis. It too is inherited, although the mutation is not in the *HFE* gene, but rather in an as-yet-unidentified gene on chromosome 1q[152] or in hepcidin.[151]

A dominantly inherited form of iron storage disease results from mutations in ferroportin (SLC11A3).[37,50,124,125] Here iron storage occurs primarily in macrophages, not in liver parenchyma. Iron accumulation appears to be more common in Africans than Europeans, and although diet may play a major role, it is thought that there is also a genetic predisposition that may account for the increased iron burden.[71]

Anemias With Iron Storage

The most common cause of iron overload is thalassemia, particularly in the parts of the world where it is prevalent (see earlier section). Indeed, the cardiac complications of iron overload are among the most common causes of death in β-thalassemia major. *Sideroblastic anemias* are a group of iron-loading disorders, many of which are of unknown cause. In a hereditary type of this disorder, there is deficiency of erythroid specific 5-aminolevulinic acid synthetase in RBC precursors because of mutations involving the X-linked gene that encodes this enzyme.[38] Iron storage is common in patients with congenital dyserythropoietic anemia[11,158] and may be found in patients with red cell enzyme deficiencies, particularly pyruvate kinase deficiency.[48]

BILIRUBIN

Bilirubin is the orange-yellow pigment derived from senescent red blood cells. It is extracted and biotransformed mainly in the liver, and excreted in bile and urine. The chemistry, biochemistry, and analytical methodology for bilirubin and related compounds are reviewed in this section.

CHEMISTRY

Bilirubin was discovered by Virchow in 1849 in blood extravasates; he called the yellow pigment "hematoidin." The term "bilirubin" was coined by Stadeler in 1864, and in 1874 Tarchanoff demonstrated the direct association of bile pigments to Hb. In 1942 Fisher and Plieninger synthesized bilirubin IXα and proposed the structure shown in the upper portion of Figure 31-20. This linear tetrapyrrolic structure of the bilirubin molecule was accepted for more than 30 years. However, an important and puzzling chemical property of the bilirubin molecule is its insolubility in water and its solubility in a variety of nonpolar solvents. The solubility of bilirubin in nonpolar, lipid solvents is not predicted from this linear tetrapyrrole structure, because the two propionic acid side chains would be expected to make the bilirubin molecule highly polar and therefore water soluble.

The overall chemical structure of bilirubin was established by x-ray crystallography.[24] According to this work, bilirubin assumes a ridge-tiled configuration stabilized by six intramolecular hydrogen bonds. Two additional important structural features have also been noted: (1) a so-called Z-Z *(trans)* conformation for the double bonds between carbons 4 and 5 and 15 and 16, and (2) an involuted hydrogen-bonded structure in which the propionic acid–carboxylic acid groups are hydrogen bonded to the nitrogen atoms of the pyrrole rings (Figure 31-20, bottom). These bonds sta-

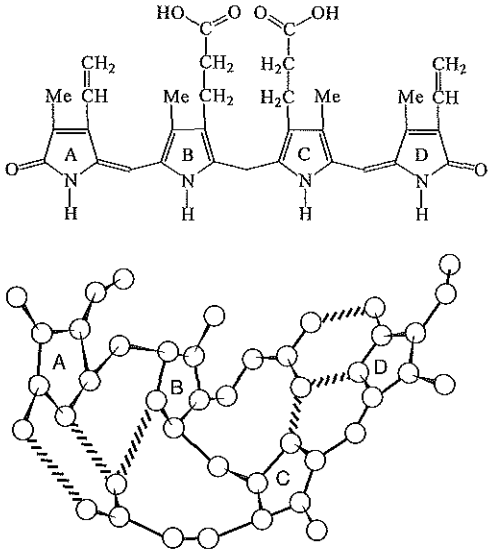

Figure 31-20 Bilirubin IXα structure. *Top,* The unfolded or linear tetrapyrrole structure showing the Z bonds. *Bottom,* The folded conformation showing extensive internal hydrogen bonding. *(Reprinted by permission of Elsevier Science Publishing Co., Inc., from Schmid, R. Bilirubin metabolism: State of the art. Gastroenterology 1978;74:1307-12, with permission from the American Gastroenterological Association.)*

bilize the Z-Z configuration of bilirubin and prevent its interaction with polar groups in aqueous media. When exposed to light, the Z-Z configuration is converted to the E-E *(cis)* conformation and to other combinations, namely 4E-15Z and 4Z-15E. The E-E conformation and other E-containing isomers do not permit the degree of internal hydrogen bonding that occurs in the Z-Z conformation and are therefore more water soluble than in the Z-Z conformation. Thus light-exposed forms of bilirubin are more water soluble and readily excreted in the bile. This is the rationale for irradiating jaundiced newborns with 450 nm light.[117]

The bilirubin molecule in the crystalline state takes, as mentioned above, the form of a ridge tile rather than a linear tetrapyrrole, with the ridge being along the line C8-C10-C12. In this configuration, rings A and B lie in one plane and rings C and D in another, with a 98° angle between the two rings. The preferred conformation of bilirubin in aqueous solution at pH 7.4 is not known, but the occurrence of a hydrogen-bonded structure in aqueous solution would explain some of the unique chemical properties of bilirubin IXα. For example, the addition of hydrogen bond–breaking chemicals—such as caffeine, methanol, ethanol, urea, or surface active agents—is required for unconjugated bilirubin to react with diazo reagent. These reagents likely act by breaking internal hydrogen bonds of the bilirubin molecule, allowing it to react with diazotized sulfanilic acid or other diazo compounds. In contrast, bilirubin IXα monoglucuronide and diglucuronide are quite soluble in water and react readily with diazo reagents. The bulky glucuronic acid moiety precludes conjugated bilirubin from undergoing internal hydrogen bond formation. Bilirubin glucuronides, being water soluble, are readily excreted in the bile and urine, whereas unconjugated bilirubin is not.

Bilirubin deriving from natural sources consists almost entirely (99%) of the IXα. Bilirubins IXβ and IXδ, arising from the cleavage of the β- and δ-methene bridges, consist of less than 0.5% of bilirubin isolated from bile. However, bilirubin reference materials available from commercial sources, and from the National Institute of Standards and Technology (Standard Reference Material 916a) contain variable amounts of IIIα and XIIIα isomers.[115] The two isomers are formed by cleavage of bilirubin IXα at the central methylene bridge; subsequent recombination of the two different dipyrrole units gives a mixture of the three isomers. This isomerization of bilirubin occurs in aqueous solution at acidic or neutral pH, but not when bilirubin is bound to albumin.[116]

Biochemistry

Bilirubin IXα is produced from the catabolism of protoporphyrin IX by a microsomal heme oxygenase. The tetrapyrrolic product of the ring opening at the α-methene bridge is the green pigment biliverdin, which is subsequently reduced to bilirubin by the reduced form of nicotinamide adenine dinucleotide phosphate (NADPH)–dependent, cytosolic enzyme biliverdin reductase (Figure 31-21). For

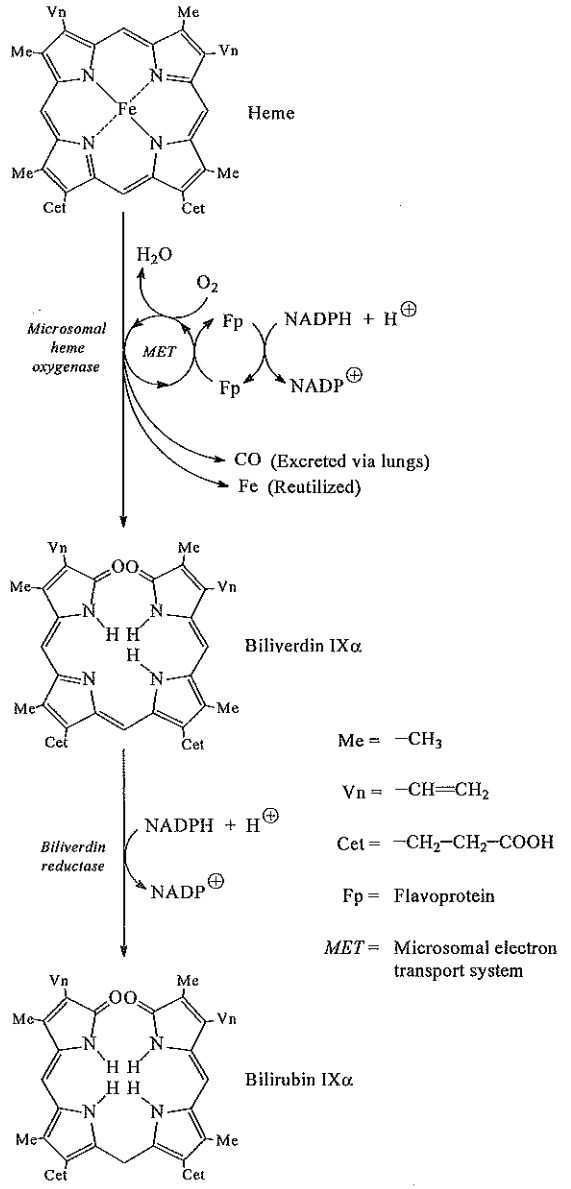

Figure 31-21 Catabolism of heme to bilirubin IXα. *(From Berlin, N.I., Berk, P.D.: Quantitative aspects of bilirubin metabolism for hematologists. Blood, 57:983-999, 1981.)*

each mole of heme catabolized by this pathway, one mole each of carbon monoxide, bilirubin, and ferric iron is produced. Daily bilirubin production from all sources in man averages from 250 to 300 mg. Approximately 85% of the total bilirubin produced is derived from the heme moiety of Hb released from senescent erythrocytes that are destroyed in the reticuloendothelial cells of the liver, spleen, and bone marrow. The remaining 15% is produced from RBC precursors destroyed in the bone marrow (so-called ineffective erythropoiesis) and from the catabolism of other heme-containing proteins, such as myoglobin, cytochromes, and peroxidases.

In blood, bilirubin is bound to albumin ($K_d \sim 10^{-8}$ mol/L) and transported to the liver. Bilirubin then dissociates from

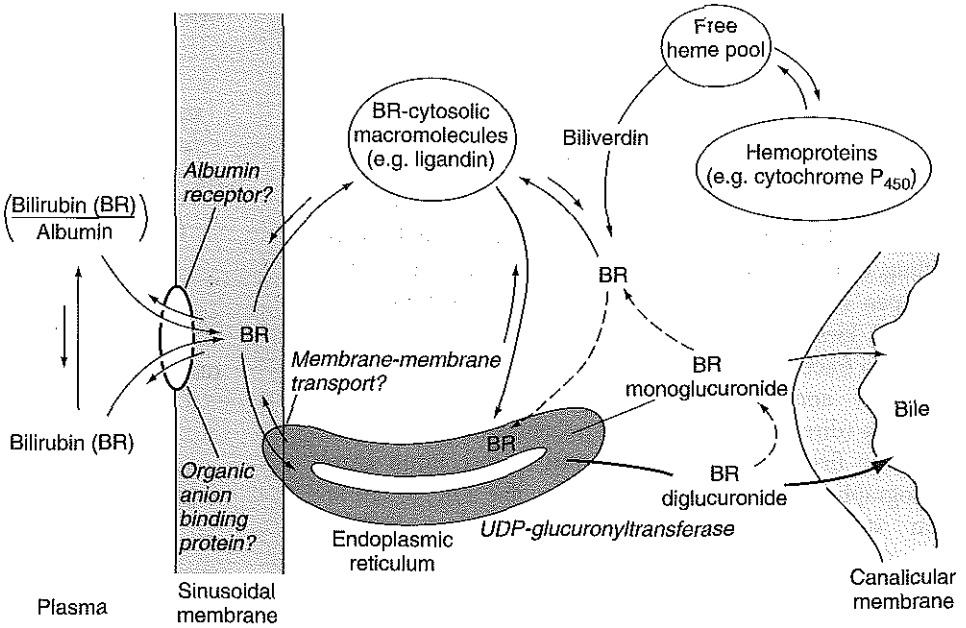

Figure 31-22 Bilirubin uptake, metabolism, and transport in the hepatocyte. *(From Gollan JL, Schmid R. In Popper H, Schaffner F, Eds. Progress in liver diseases, Vol. 7, Chapter 15. Philadelphia: WB Saunders Company, 1982.)*

albumin by an unknown process at the sinusoidal membrane of the hepatocyte. It is then transported across the membrane (Figure 31-22). Once inside the liver cells, bilirubin is reversibly bound to soluble proteins known as ligandins or protein Y. Ligandins are cytosolic proteins of the glutathione-S-transferase gene family and constitute ~5% of the total protein of human liver cytosol. Ligandin also binds a variety of other compounds, such as steroids, bromsulfthalein (BSP), indocyanine green, and some carcinogens. Ligandin likely plays an important role in the processing of these compounds; it may increase the net efficiency of uptake by retarding the reflux of these substances back to plasma.

Inside the hepatocytes, bilirubin is rapidly conjugated with glucuronic acid to produce bilirubin monoglucuronide and diglucuronide, which are then excreted into bile (see Figure 33-22). The microsomal enzyme bilirubin uridine diphosphate (UDP)–glucuronyltransferase (EC 2.4.1.17) catalyzes the formation of bilirubin monoglucuronide. It is not certain whether the conversion of the monoglucuronide to the diglucuronide is catalyzed by the same enzyme or by another enzyme located in or near the canaliculus. The excretion of conjugated bilirubin into bile against a marked concentration gradient is thought to be an energy-dependent, active-transport process.

In adults, virtually all bilirubin excreted in bile is in the form of glycosidic conjugates; glucuronides account for ~95% of them and glucosides and xylosides constitute the remainder. Of the glucuronides, diglucuronide is the major fraction (~90%) and monoglucuronide the minor fraction (~10%).

Bilirubin glucuronides are not substantially reabsorbed in the intestine. Rather, they are hydrolyzed by the catalytic action of β-glucuronidase from the liver, intestinal epithelial cells, and bacteria. This unconjugated bilirubin is then reduced by anaerobic intestinal microbial flora to form a group of three colorless tetrapyrroles collectively called *urobilinogens.* In each of these three bilirubin reduction products, all bridge carbons are in the saturated (methylene) form. The urobilinogens differ from one another in the degree of hydrogenation of the vinyl side chains and in the two end pyrrole rings; urobilinogens contain 6, 8, or 12 more hydrogen atoms than does bilirubin and are named *stercobilinogen, mesobilinogen,* and *urobilinogen,* respectively. Up to 20% of the urobilinogen produced daily is reabsorbed from the intestine and enters the enterohepatic circulation. Most of the reabsorbed urobilinogen is taken up by the liver and is reexcreted in the bile; a small fraction (2% to 5%) enters the general circulation and appears in urine. In the lower intestinal tract, the three urobilinogens spontaneously oxidize at the middle methylene bridge to produce the corresponding bile pigments stercobilin, mesobilin, and urobilin, which are orange-brown and the major pigments of stool. Approximately 50% of the conjugated bilirubin excreted in bile is metabolized to products other than the urobilinogens. The detailed structure of these metabolites has not been characterized.

Analytical Methodology

Several analytical techniques are used to measure bilirubin and metabolites in serum, urine, and feces.*

Serum Bilirubin

The reaction of bilirubin with diazotized sulfanilic acid, known as the diazo reaction, discovered by Ehrlich in 1883

*Methodologal details for methods discussed in this section are included in this book's accompanying Evolve site, found at http:/evolve.elsevier.com/Tietz/textbook/.

and applied to the measurement of bilirubin in serum and bile by van den Bergh and Muller in 1916, is the basis of the most widely used methods for measuring bilirubin. The observation that in sera from jaundiced infants the reaction was slow and required an accelerator to proceed and it was fast in bile and in adult sera without addition of ethanol led to the terms "direct" and "indirect" bilirubin. The chemical nature of direct and indirect bilirubins was elucidated by Billing, Cole, and Lathe in the mid-1950s.[18] They isolated by an open column reversed phase chromatography on siliconized kieselguhr (cellite or diatomaceous earth) three bilirubin fractions, unconjugated bilirubin (indirect reacting fraction), and bilirubin monoglucuronide and diglucuronide (direct reacting fractions). Kuenzle and colleagues[97] were the first to successfully use an open-column chromatography technique that did not involve a deproteinization step. Four bilirubin fractions were obtained: unconjugated bilirubin (α-bilirubin), monoconjugated bilirubin (β-bilirubin), diconjugated bilirubin (γ-bilirubin), and a fraction bound strongly to protein (δ-bilirubin). The last fraction was clearly distinct from the albumin-bilirubin complex that exists in serum.

Diazo Methods

The most widely used chemical methods for bilirubin measurement are those based on the diazo reaction.[108a] In this reaction, diazotized sulfanilic acid (the diazo reagent) reacts with bilirubin to produce two azodipyrroles (azopigments) (Figure 31-23), which are reddish purple at neutral pH and blue at low or high pH values. Van den Bergh and Muller[171] applied this reaction to the quantitation of bilirubin in serum. They described the fraction of bilirubin that reacted with the diazo reagent in the absence of alcohol as the direct bilirubin fraction and used the term indirect bilirubin for the difference between total bilirubin (found after the addition of alcohol to the reaction mixture) and the direct bilirubin fraction. Numerous variations of the van den Bergh method have been developed. All use one of a variety of "accelerators," which like alcohol, facilitate the reaction of unconjugated (indirect) bilirubin with the diazo reagent; the most commonly used accelerators are caffeine,[93] dyphylline,[118] and a number of surface active agents. The diazo method of Malloy and Evelyn,[112] which uses methanol as an accelerator, has substantial matrix effects, negative interference by Hb, turbidity due to protein precipitation by methanol, and a relatively long reaction time.[52] This method, which has been virtually abandoned, is mentioned here for historical reasons only.

The diazo method described by Jendrassik and Grof in 1938[93] and later modified by Doumas and colleagues[137] gives results for serum total bilirubin that are reproducible and reliable. In this procedure, an aqueous solution of caffeine and sodium benzoate serves as the accelerator. Studies on the mechanism by which the caffeine-benzoate solution facilitates the reaction of unconjugated bilirubin with the diazo reagent have provided strong, albeit indirect, evidence that

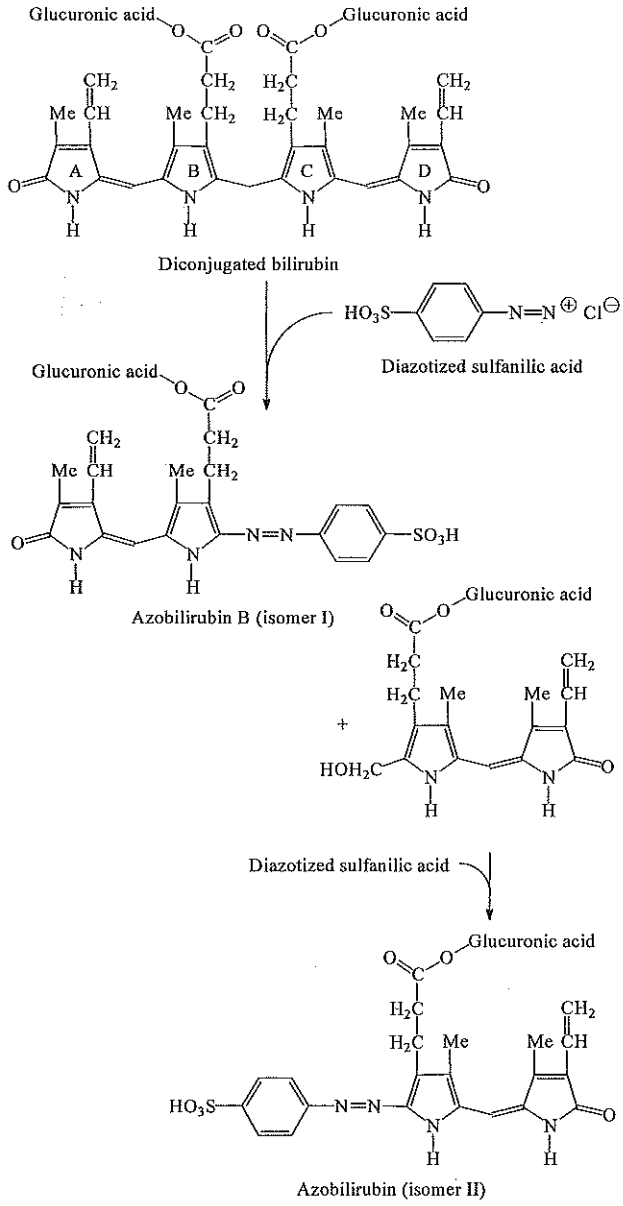

Figure 31-23 The reaction of bilirubin glucuronide with diazotized sulfanilic acid to produce isomers I and II of azobilirubin B. Unconjugated bilirubin reacts in the same way to produce isomers I and II of azobilirubin A.

caffeine, and perhaps benzoate, displaces unconjugated bilirubin from its association sites on albumin. This occurs by (1) formation of hydrogen bonds between bilirubin and caffeine,[67,101] thus making bilirubin water soluble, or (2) complex formation and disruption of the bilirubin internal hydrogen bonds. By use of samples prepared by addition of unconjugated bilirubin and authentic human diconjugated bilirubin to low-bilirubin pooled sera—and a nuclear magnetic resonance technique—Lo and Wu[108] have shown that the modified Jendrassik-Grof total bilirubin assay detects unconjugated and diconjugated bilirubin quantitatively (as unconjugated bilirubin equivalents). This method has

acceptable transferability among laboratories and is currently the method of choice.

Other methods for determining bilirubin include direct spectrophotometric measurement of total bilirubin in serum using analysis of a two-component system (i.e., measuring absorbance at two wavelengths and solving a system of two simultaneous equations). This approach is applicable to sera from healthy neonates because only unconjugated bilirubin is present in such sera. Correction for oxyhemoglobin is necessary, because it is invariably present in sera from neonates (For further details see Analytical Methods in this book's accompanying Evolve site, found at http:/evolve.elsevier.com/Tietz/textbook/.

High-Performance Liquid Chromatography

HPLC methods have also been developed that allow for relatively rapid separation and quantification of the four bilirubin fractions. HPLC has been helpful in detecting and separating the various bilirubin photoisomers produced during phototherapy in newborns and thus in elucidating the mechanism by which phototherapy lowers the concentration of bilirubin in the newborn blood.[117] There are several versions of HPLC for analysis of bilirubin fractions. In the method of Blanckaert,[22] bilirubin conjugates, but not unconjugated bilirubin, are converted to the corresponding bilirubin methyl esters by base-catalyzed transesterification in methanol followed by extraction with chloroform. With this procedure, the α-, β-, and γ-bilirubin fractions are recoverable, but the δ-fraction (delta-bilirubin) remains in the denatured protein pellet that is produced by the chloroform extraction. In the HPLC method of Lauff and coworkers,[103] all four bilirubin fractions remain in solution after a step that involves salting out globulins with sodium sulfate. Both methods require the use of dim incandescent or yellow light to minimize photodegradation of the various bilirubin species. A simple and fast HPLC method has been published by Adachi et al[1]; the method uses a Micronex RP-30 column, which does not require salting out of globulins or chemical transformation of the bilirubin conjugates. This method separates serum bilirubin into five fractions; the fifth fraction eluted between the monoglucuronide and the unconjugated bilirubin is the Z,E or the E,Z photoisomer. The elution sequence is the same as in the procedure of Lauff.[103]

Additional studies indicated that the δ-bilirubin fraction consists of one or more bilirubin species that are covalently bound to albumin.[104] Existence of covalent linkage is supported by the fact that the associated bilirubin species are not released from the albumin fraction by treatment with strong acid or base or a variety of strong denaturing agents, by hydrolysis with proteolytic enzymes, or by boiling in methanol. The δ-bilirubin reacts directly with diazotized sulfanilic acid. The discovery of δ-bilirubin has solved the mystery of the persisting high bilirubin concentrations, mostly direct reacting, in patients with intrahepatic or obstructing jaundice long after hepatitis has subsided or obstruction has been relieved. It is the slowest fraction to clear from serum because it follows the catabolism of albumin, which has a half-life of approximately 19 days.

From HPLC analyses of a large number of sera from patients with various liver disorders, Wu and colleagues[185] found the following proportions of the four bilirubin fractions in cholestatic sera: 27% (8% to 55%) unconjugated bilirubin, 24% (8% to 37%) monoconjugated bilirubin, 13% (7% to 21%) diconjugated bilirubin, and 37% (1% to 77%) δ-bilirubin.

HPLC has been very helpful in elucidating the nature of the bilirubin species occurring naturally in blood or formed during phototherapy. Clinically, it offers little, if any, aid to the physician in the differential diagnosis of jaundice, because knowing the percentage of each of the bilirubin fractions in blood is of no diagnostic value. It cannot be considered as a reference method for measuring total bilirubin in blood, because its accuracy and precision are inadequate. The method is calibrated with unconjugated bilirubin with the untested assumption that the other three bilirubin fractions have molar absorptivities identical to that of the calibrator,[102] when in fact this is not known. Furthermore, errors in the measurement of the four species may be cumulative and may result in a large total error, and the method is insensitive at total bilirubin concentrations below 1 mg/dL (17 μmol/L) and too laborious for routine clinical analysis. Some of the δ-bilirubin may be lost during pretreatment of samples.

A capillary electrophoresis method for measuring the different types of bilirubin has been developed by Wu and his associates.[184]

Enzymatic Methods

Enzymatic methods for total and direct bilirubin and for bilirubin conjugates with glucuronic acid are based on the oxidation of bilirubin with bilirubin oxidase to biliverdin with molecular oxygen.[121] Near pH 8 and in the presence of sodium cholate and sodium dodecylsulfate, all four bilirubin fractions are oxidized to biliverdin, which is further oxidized to purple and finally colorless products. The decrease in absorbance, at 425 or 460 nm, is proportional to the concentration of total bilirubin. Results by the bilirubin oxidase method were in good agreement with those obtained by the Jendrassik-Grof procedure.[136] Direct bilirubin is measured at pH 3.7 to 4.5; at this pH range, the enzyme oxidizes bilirubin conjugates and δ-bilirubin, but not unconjugated bilirubin.[51,96] At pH 10 the enzyme oxidizes selectively the two glucuronides.[53,96] δ-bilirubin is not oxidized at all, and only 5% of the unconjugated bilirubin is measured as conjugates.[53]

Transcutaneous Measurement of Bilirubin

This noninvasive approach for measuring bilirubin was introduced by Yamanouchi et al.[187] The first bilirubinometer (icterometer) was a reflectance photometer, which used two filters to correct for the color of Hb and required measure-

ments at eight body sites. Efforts to improve the accuracy of such measurements have been successful and led to the development of devices of acceptable performance. Recent reports indicate that at least one of these devices (Bili*Check* ($SpectR_x$ Inc., Norcross, Ga.) provides results that are within ±2 mg/dL of those obtained by a diazo procedure.[16,147] Another study found that the Bili*Check* underestimated serum bilirubin when its concentration was >10 mg/dL (170 μmol/L).[55]

Although transcutaneous bilirubin measurements may not substitute for laboratory quantitative determinations, they provide instantaneous information, reduce the necessity for serum bilirubin determinations, spare infants the trauma of heel sticks, and save money.[111] Furthermore, they are useful in determining whether in a jaundiced infant it is necessary to draw blood to guide treatment, such as phototherapy or exchange transfusion. Another application is predicting those babies that require follow-up according to the "hour-specific" serum bilirubin nomogram by Bhutani et al.[17]

Urine Bilirubin

Because only conjugated bilirubin is excreted in urine, its presence indicates conjugated hyperbilirubinemia. The most commonly used method for detecting bilirubin in urine involves the use of a dipstick impregnated with a diazo reagent. Dipstick methods can detect bilirubin concentrations as low as 0.5 mg/dL.

A fresh urine specimen is required because bilirubin is unstable when exposed to light and room temperature, and it may be oxidized to biliverdin (which is diazo negative) at the normally acidic pH of the urine. If the test is delayed, the sample must be protected from light and stored at 2 °C to 8 °C for no longer than 24 hours. The reagent strip (Chemstrip, Roche Diagnostics; Multistix, Bayer Corp.) is immersed into the urine specimen for no longer than 1 second and is read 60 seconds later. During this time bilirubin reacts with a diazo reagent, yielding a pink to red-violet color, the intensity of which is proportional to the bilirubin concentration. The reaction mechanism for urinary conjugated bilirubin is the same as that described in Figure 31-23 except that 2,6-dichlorobenzene-diazonium-tetrafluoroborate is substituted for diazotized sulfanilic acid in the Chemstrip, and 2,4-dichloroaniline diazonium salt in the Multistix. Another commonly used test, more sensitive than the Multistix, is the Ictotest reagent tablet (Bayer Corporation); in this semiquantitative procedure the diazo reagent is *p*-nitrobenzenediazonium-*p*-toluenesulfonate.

The Chemstrip and Multistix strips for bilirubin in urine are highly specific tests and have a low incidence of false-positive results. However, medications that color the urine red or that give a red color in an acid medium, such as phenazopyridine, can produce a false-positive reading. Large quantities of ascorbic acid or of nitrite also worsen the detection limit of the test. In practice, bilirubin is rarely measured in urine.

Urobilinogen in Urine and Feces

An increase in urobilinogen in the urine occurs whenever hepatocellular function is decreased or there is an excess of urobilinogen in the gastrointestinal (GI) tract that exceeds the liver's capacity to reexcrete it. Examples of such conditions are viral hepatitis, cirrhosis, and hemolysis. In contrast, when biliary excretion of bilirubin (e.g., cholestasis) is impaired, urinary excretion of urobilinogen decreases owing to the limited delivery of bilirubin to the gut. The clay-colored or chalky white stool of patients with cholestatic jaundice results from decreased bilirubin reaching the GI tract and the subsequent low quantities of metabolites produced. These disturbances of urobilinogen excretion are the basis for the historical use of urobilinogen analysis in urine and feces as an index of liver disease. However, urobilinogen measurement is of little help in the modern evaluation of liver disease, because it does not add to the diagnostic information obtained from the commonly performed tests described in the section on diagnostic strategy. A brief description of the measurement of urobilinogen in urine and feces can be found in the 3rd edition of this textbook on page 1137.

Clinical Significance

Defects in bilirubin metabolism resulting in jaundice can occur at each step of the metabolic pathway (see Figure 31-22). The disorders are usually classified as (1) inherited disorders of bilirubin metabolism and (2) jaundice of the newborn. All of these disorders are characterized by predominant elevations in either conjugated or unconjugated bilirubin in the absence of other abnormal liver tests. It is only in these disorders that bilirubin fractionation is clinically useful.

Patients are occasionally seen with isolated elevations in bilirubin concentration. In most cases this is due to inherited disorders of bilirubin metabolism, familial hyperbilirubinemia, or hemolysis. It is not difficult to distinguish hemolysis severe enough to cause hyperbilirubinemia, because the patient with hemolysis will have many other disease manifestations. An algorithm for differentiating the familial causes of hyperbilirubinemia is presented in Figure 31-24. Isolated hyperbilirubinemia was discussed in a previous section on disorders of bilirubin metabolism.

Inherited Disorders of Bilirubin Metabolism

Inherited disorders of bilirubin metabolism include Gilbert's, Crigler-Najjar (Type I), Crigler-Najjar (Type II), Lucey-Driscoll, Dubin-Johnson, and Rotor's syndromes.

Gilbert Syndrome

Gilbert syndrome is a benign condition manifested by mild unconjugated hyperbilirubinemia. This abnormality, affecting 3% to 5% of the population, is clinically important, because it is often misdiagnosed as chronic hepatitis. The serum concentration of bilirubin fluctuates between 1.5 and 3 mg/dL (26 and 51 μmol/L) and tends to increase with

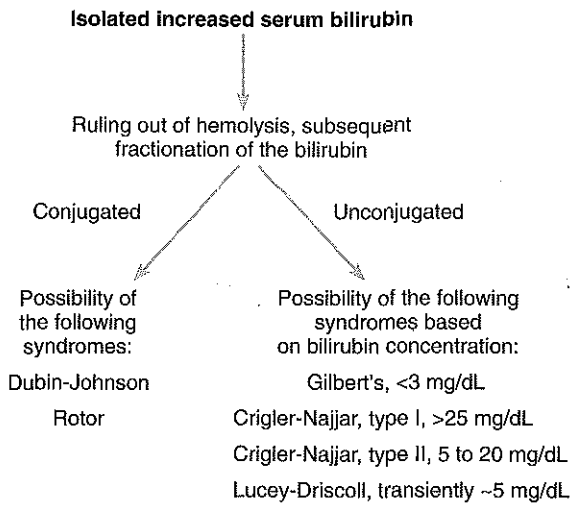

Figure 31-24 Algorithm for differentiating the familial causes of hyperbilirubinemia.

fasting. Hepatic glucuronyltransferase activity is low as a consequence of a mutation in the bilirubin-UDP-glucuronosyltransferase (*UGT1A1*) gene. In the vast majority of patients, this mutation is a repeat in the promoter, so that there are seven rather than the "normal" six ATs.[25] Occasionally, subjects with only five and as many as eight repeats are encountered; the transcription of the gene is inversely proportional to the number of repeats,[14] so that bilirubin levels tend to be higher in those patients with the largest number of repeats in the promoter. In Asia, Gilbert syndrome has sometimes been found to be caused by a single point mutation in exon 1 of the *UGT1A1* gene.[95] Gilbert syndrome is easily distinguished from chronic hepatitis by the absence of anemia and bilirubin in urine, and by normal liver function tests. The condition is probably inherited as an autosomal recessive trait. Despite the fact that total biliary bilirubin is reduced, there is an increase in the ratio of bilirubin monoglucuronide to diglucuronide, suggesting that there is also a defect in the conversion of bilirubin monoglucuronide to diglucuronide.

Patients with Gilbert syndrome may be predisposed to acetaminophen toxicity since acetaminophen is primarily metabolized by glucuronidation. The diagnosis is usually made by chance on routine medical examination or when jaundice occurs following an intercurrent infection or fasting. Special diagnostic tests are occasionally necessary and include demonstrating a rise in bilirubin on fasting and a fall in bilirubin upon taking phenobarbital. No treatment is needed, but patients must be reassured that they do not have liver disease.

Crigler-Najjar Syndrome (Type I)

Crigler-Najjar syndrome type I is a rare disorder caused by complete absence of UDP-glucuronyltransferase and manifested by very high levels of unconjugated bilirubin (25 to 50 mg/dL). It is inherited as an autosomal recessive trait. Most patients die of severe brain damage caused by kernicterus (encephalopathy related to increased bilirubin that leads to permanent brain damage) within the first year of life. Phlebotomy and plasmapheresis can reduce the serum bilirubin, but encephalopathy usually develops. Early liver transplantation is the only effective therapy.

Crigler-Najjar Syndrome (Type II)

This is a rare autosomal dominant disorder characterized by a partial deficiency of UDP-glucuronyltransferase. Unconjugated bilirubin is usually 5 to 20 mg/dL (85 to 340 μmol/L). Unlike the Crigler-Najjar syndrome type I, type II responds dramatically to phenobarbital and a normal life can be expected.

Lucey-Driscoll Syndrome

Lucey-Driscoll syndrome is a familial form of unconjugated hyperbilirubinemia caused by a circulating inhibitor of bilirubin conjugation. The hyperbilirubinemia is mild and lasts for the first 2 to 3 weeks of life.

Dubin-Johnson Syndrome

Dubin-Johnson syndrome is a benign, autosomal recessive condition characterized by jaundice with predominantly elevated conjugated bilirubin and a minor elevation of unconjugated bilirubin. Excretion of various conjugated organic anions and bilirubin, but not bile salts, into bile is impaired, reflecting the underlying defect in canalicular excretion. Intravenous cholangiography does not show the gallbladder, but a ^{99m}Tc-hepatobiliary iminodiacetic acid (HIDA) scan does. There is a derangement in the excretion of urinary coproporphyrin; the normal ratio of coproporphyrin I to III is reversed. The liver has a characteristic greenish black appearance and liver biopsy reveals a dark brown pigment in hepatocytes and Kupffer's cells that looks like lipofuscin but is probably melanin. Serum alanine aminotransferase and alkaline phosphatase are usually normal, and pruritus is absent. The condition is benign, although patients may develop jaundice during pregnancy or while taking oral contraceptives.

Rotor Syndrome

Rotor syndrome is another form of conjugated hyperbilirubinemia similar to Dubin-Johnson syndrome but without pigment in the liver. The gallbladder is seen on intravenous cholecystography. Total urinary coproporphyrins are elevated, with about two thirds being coproporphyrin I. The prognosis is excellent.

Jaundice in the Neonate

Disorders that cause jaundice in the neonate are classified as either unconjugated or conjugated hyperbilirubinemia (see Box 31-1).[121a]

Unconjugated Hyperbilirubinemia

Unconjugated hyperbilirubinemia poses a risk for development of kernicterus (acute bilirubin encephalopathy), espe-

Box 31-1 Physiological Classification of Jaundice

Unconjugated Hyperbilirubinemia

Increased Production of Unconjugated Bilirubin from Heme

- Hemolysis
  - Hereditary
  - Acquired
- Ineffective erythropoiesis
- Rapid turnover of increased RBC mass (in the neonate)

Decreased Delivery of Unconjugated Bilirubin (in Plasma) to Hepatocyte

- Right-sided congestive heart failure
- Portacaval shunt

Decreased Uptake of Unconjugated Bilirubin Across Hepatocyte Membrane

- Competitive inhibition
  - Drugs
  - Others
- Gilbert's syndrome
- Sepsis, fasting

Decreased Storage of Unconjugated Bilirubin in Cytosol (Decreased Y and Z Proteins)

- Competitive inhibition
- Fever

Decreased Biotransformation (Conjugation)

- Neonatal jaundice (physiological)
- Inhibition (drugs)
- Hereditary (Crigler-Najjar)
  - Type I (complete enzyme deficiency)
  - Type II (partial deficiency)
- Hepatocellular dysfunction
- Gilbert's syndrome

Conjugated Hyperbilirubinemia (Cholestasis)

Decreased Secretion of Conjugated Bilirubin into Canaliculi

- Hepatocellular disease
  - Hepatitis
  - Cholestasis (intrahepatic)
- Dubin-Johnson and Rotor's syndromes
- Drugs (estradiol)

Decreased Drainage

- Extrahepatic obstruction
  - Stones
  - Carcinoma
  - Stricture
  - Atresia
- Sclerosing cholangitis
- Intrahepatic obstruction
  - Drugs
  - Granulomas
  - Primary biliary cirrhosis
  - Bile duct paucity
  - Tumors

cially in low-birth-weight infants. Kernicterus refers to a neurological syndrome that results in brain damage owing to deposition of bilirubin in the basal ganglia and brainstem nuclei. In term infants the early symptoms of kernicterus are poor feeding, lethargy, and vomiting; later opisthotonos (backward arching of the trunk), seizures, and death may follow. Seventy percent of affected infants die within the first week and the remaining have severe brain damage. This syndrome can be prevented by phototherapy and exchange transfusion in infants with elevated unconjugated bilirubin concentrations.

Causes of unconjugated hyperbilirubinemia in the neonate are physiological jaundice of the newborn, hemolytic disease, and breast milk hyperbilirubinemia.

Physiological Jaundice of the Newborn. Babies frequently become jaundiced within a few days of birth, a condition known as physiological jaundice of the newborn. Bilirubin levels reach a peak within 3 to 5 days of birth and remain elevated for less than 2 weeks. Bilirubin is usually less than 5 mg/dL, with 90% unconjugated. Factors contributing to physiological jaundice are (1) an increased bilirubin load in the newborn because the RBCs have a shortened lifespan, (2) the appearance of "shunt" bilirubin, which is bilirubin derived from ineffective erythropoiesis or non-RBC sources, (3) decreased conjugation of bilirubin owing to a relative lack of glucuronyl transferase (conjugating enzyme) in the first few days following birth, (4) increased absorption of bilirubin in the intestine owing to beta-glucuronidase in meconium, which hydrolyzes bilirubin conjugates to unconjugated bilirubin that can be passively reabsorbed, and (5) exposure of breast-feeding infants to pregnanediol, nonesterified fatty acids, and other inhibitors of bilirubin conjugation present in the breast milk.

Bilirubin concentrations of 13 mg/dL (222 μmol/L) or greater occurred in 6% of 2297 infants who weighed more than 2500 g.[110] Physiological jaundice is generally not harmful, but bilirubin levels above 10 mg/dL (170 μmol/L) coupled with prematurity, low serum albumin, acidosis, and substances that compete for the binding sites of albumin (e.g., ceftriaxone, sulfisoxazole, and aspirin) may increase the risk for kernicterus. Physiological jaundice of the newborn is treated with phototherapy; the infant is exposed to light of approximately 450 nm that disrupts the intramolecular hydrogen bonds in the bilirubin molecule and yields a number of photoisomers that are more water-soluble than the Z,Z-isomer and thus excreted in the bile.[117] Exchange transfusions are rarely necessary.

Hemolytic Disease. Hemolytic disease in the newborn results from maternal-fetal incompatibility of Rhesus blood factors in which the maternal Rh-negative blood becomes

sensitized by either a previous pregnancy with an Rh-positive fetus or an Rh-positive blood transfusion. The infant becomes jaundiced with unconjugated bilirubin in the first or second day of life and is susceptible to kernicterus. The diagnosis is confirmed by a Coombs' test in the infant, an Rh-positive blood in the infant and Rh-negative blood in the mother. Other rare inherited hemolytic anemias, such as glucose-6-phosphate dehydrogenase (G6PD) deficiency, may also lead to unconjugated hyperbilirubinemia.

Breast Milk Hyperbilirubinemia. This type of hyperbilirubinemia affects about 30% of breast-fed newborns. It is due to α-glucuronidase in breast milk, which hydrolyzes conjugated bilirubin in the intestine. The unconjugated bilirubin, being more lipophilic, is passively absorbed. The condition lasts for a few weeks and is treated by discontinuing breast feeding.

Conjugated Hyperbilirubinemias

These syndromes are characterized by hyperbilirubinemia in which the conjugated bilirubin exceeds 1.5 mg/dL (24 μmol/L). The most important are idiopathic neonatal hepatitis and biliary atresia. Diagnosing the cholestatic syndromes may be difficult. The family history may be helpful in diagnosing α_1-antitrypsin deficiency, cystic fibrosis, galactosemia, hereditary fructose intolerance, and tyrosinosis. Serum tyrosine and α_1-antitrypsin levels should be obtained. Urinary nonglucose-reducing substances are obtained if galactosemia is suspected; the diagnosis is confirmed by the absence of the enzyme UDP galactose-1-phosphate uridyl transferase in cells and tissues, such as RBCs and liver. Serological tests may be necessary for hepatitis A, B, and C, and for adenovirus, coxsackievirus, cytomegalovirus, herpes simplex, rubella, and *Toxoplasma*. Liver biopsy may be performed, but the liver tends to look similar, with giant cells and extramedullary erythropoiesis dominating in both hepatitis and cholestatic syndromes. The typical features of periportal red hyaline globules seen with periodic acid-Schiff (PAS) stain that are characteristic for α_1-antitrypsin deficiency are usually not seen early in the course of the disorder. An HIDA isotope scan is essential for determining the patency of the biliary tree. Percutaneous or endoscopic cholangiography may be done in patients with equivocal HIDA scan results.

Conjugated hyperbilirubinemia is seen fairly often in the newborn as a complication of parenteral nutrition.

Idiopathic Neonatal Hepatitis

About 75% of cases of hepatitis in the neonate are idiopathic giant cell hepatitis, a disorder of unknown etiology characterized by cholestatic jaundice. There is a familial trend that may reflect an autosomal recessive inheritance. Jaundice appears within the first 2 weeks. The child initially appears well and gains weight. The liver and spleen then become enlarged and stools become pale. Serum aminotransferases are usually >400 U/L; the prothrombin time is prolonged. Liver biopsy reveals characteristic giant cells with hepatocyte acinar formation. Cholestasis is prominent. It is important to rule out extrahepatic biliary obstruction, such as occurs in biliary atresia, with an HIDA scan.

The treatment is supportive, with adequate nutrition and correction of hypoprothrombinemia. The prognosis is favorable, with 90% of infants surviving without sequelae.

Biliary Atresia

Biliary atresia is a heterogeneous group of acquired disorders that involve either the extrahepatic or intrahepatic bile ducts. Possible etiologies include cytomegalovirus, reovirus III, Epstein-Barr virus, rubella virus, α_1-antitrypsin deficiency, Down syndrome, and trisomy 17 or 18.

Extrahepatic biliary atresia may involve all or part of the extrahepatic biliary tree. The gallbladder is usually absent. Involvement of the hepatic or common duct leads to the characteristic syndrome of severe cholestatic jaundice. It occurs in 1 in 10,000 births, with females more commonly affected than males. Jaundice and pruritus usually appear in the first week. Stools are pale and the urine is tea colored. Jaundice is deep, but the aminotransferases are only mildly elevated. If jaundice persists beyond 14 days of age, a direct or conjugated bilirubin measurement must be performed to exclude biliary atresia. If it is elevated, the urine should be tested for bile and the stool color inspected; if the color is not green or yellow, biliary atresia is likely. Early identification of this condition is essential if these infants are to benefit from the operation of portoenterostomy, which should be performed no later than 60 days after birth.[84] If portoenterostomy is not successful, liver transplantation is the treatment of choice. Children rarely live beyond 3 years unless the lesion is surgically correctable.

Intrahepatic biliary atresia is characterized by a paucity of intrahepatic bile ducts. Jaundice usually appears within the first few days of life. Serum bilirubin is elevated and serum cholesterol may be very high and lead to the formation of xanthomas. The hepatic histology is nonspecific, showing bile duct paucity, giant cells, inflammation, and fibrosis. Survival into adolescence is common, although growth is usually retarded.

A syndromatic variant, *Alagille syndrome*, has similar features but is an autosomal dominant condition with a characteristic triangular face, skeletal abnormalities, retinal pigmentation, and pulmonary stenosis.

Treatment of intrahepatic biliary atresia is symptomatic, with intramuscular replacement of vitamins A, D, and E. Medium chain triglycerides that do not need bile acids for absorption provide calories in patients with partial atresia. Cholestyramine may relieve pruritus. Ursodeoxycholic acid reduces serum enzyme activities and relieves pruritus in some patients.

CHAPTER 32

Porphyrins and Disorders of Porphyrin Metabolism*

Allan C. Deacon, B.Sc., Ph.D., Dip.C.B., F.R.C.Path., Sharon D. Whatley, Ph.D., and George H. Elder, M.D.

The porphyrias are a group of diseases in which there is deficiency in one of the enzymes of heme biosynthesis leading to the overproduction of intermediates of the pathway.[76a] These intermediates are excreted in excessive amounts in urine, feces, or both. The clinical consequences depend on the nature of the heme precursors that accumulate. In the acute porphyrias, excess porphyrin precursors (5-aminolevulinic acid [ALA] and porphobilinogen) are associated with potentially fatal acute neurovisceral attacks, which are often provoked by a range of commonly prescribed drugs, hormonal factors, alcohol, starvation, stress, or infection. In the nonacute porphyrias, and in those acute porphyrias in which the skin may be affected, accumulation of porphyrins results in photosensitization and skin lesions. Diagnosis depends on laboratory investigation to demonstrate the pattern of heme precursor accumulation specific for each type of porphyria and requires examination of appropriate specimens for the key metabolites using adequately sensitive and specific methods.

Technical advances in the field of molecular genetics make it possible to investigate many porphyrias at the molecular level. Although not essential for diagnosis of symptomatic cases, these techniques are becoming increasingly valuable for the investigation of families with porphyria.

PORPHYRIN CHEMISTRY

Before discussing the porphyrin synthesis and disorders of porphyrin metabolism, porphyrin structure, nomenclature, and chemical characteristics are reviewed.

*The authors gratefully acknowledge the original contributions of Drs. Robert F. Labbe and Kern L. Nuttall, on which portions of this chapter are based.

Structure and Nomenclature

The basic porphyrin structure consists of four monopyrrole rings connected by methene bridges to form a tetrapyrrole ring (Figure 32-1).[15] Many porphyrin compounds are known but only a limited number are of clinical interest. The porphyrin compounds of relevance to the porphyrias (Table 32-1) differ in the substituents occupying the peripheral positions 1 through 8. Variation in the distribution of the same substituents around the peripheral positions of the tetrapyrrole ring gives rise to porphyrin isomers, which are usually depicted by Roman numerals (i.e., I, II, III etc.). The reduced form of a porphyrin is known as a porphyrinogen (see Figure 32-1) and differs by the absence of six hydrogens (four from the methylene bridges and two from ring nitrogens). Porphyrinogens are unstable in vitro and are spontaneously oxidized to the corresponding porphyrins. Under the lower oxygen tension of the cell, porphyrinogens are stable and form intermediates of the heme biosynthetic pathway; aromatization to protoporphyrin at the penultimate step requires an enzyme.

Chelation of Metals

The arrangement of four nitrogen atoms in the center of the porphyrin ring enables porphyrins to chelate various metal ions. Protoporphyrin that contains iron is known as heme; ferroheme refers specifically to the Fe^{2+} complex and ferriheme to Fe^{3+}. Ferriheme associated with a chloride counter ion is known as hemin, or hematin when the counter ion is hydroxide.

Spectral Properties

Porphyrins were named from the Greek root for "purple" (porphyra) and owe their color to the conjugated double-bond structure of the tetrapyrrole ring. The porphyrinogens

have no conjugated double bonds and are therefore colorless. Porphyrins show a particularly strong absorbance near 400 nm, often called the Soret band. When exposed to light in the 400-nm region, porphyrins display a characteristic orange-red fluorescence in the range of 550 to 650 nm. Absorbance and fluorescence are altered by substituents around the porphyrin ring and by metal binding. Zinc chelation shifts the fluorescence peak of protoporphyrin to shorter wavelengths and reduces the fluorescence intensity. The strong binding of iron alters the character of protoporphyrin to the extent that heme lacks significant fluorescence.

Solubility

Porphyrins are only marginally soluble in water. The differing solubilities of individual porphyrins are of importance not only in the design of analytical methods for their extraction and/or fractionation but in determining the route of excretion from the body. At pH 7, the carboxyl groups are ionized, and the molecule has a net negative charge. Below pH 2 the pyrrole nitrogens and the carboxyl groups become protonated so that the molecule has a net positive charge. At physiological pH, the solubility of a given porphyrin is determined by the number of substituent carboxyl groups. Uroporphyrin has eight carboxylate groups and is the most soluble porphyrin in aqueous media. Protoporphyrin has only two carboxylate groups and is essentially insoluble in water, but dissolves readily in lipid environments and binds readily to the hydrophobic regions of proteins, such as albumin. Coproporphyrin, with four carboxylate groups, has intermediate solubility.

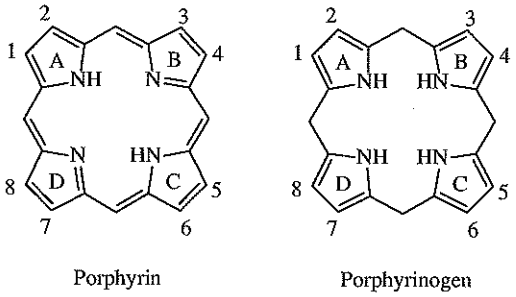

Figure 32-1 Porphyrin and porphyrinogen structures; numbers 1 to 8 represent various substituents, the nature and order of which determine the type of porphyrin or porphyrinogen (Table 32-1). Numbering system and ring designations are based on the Fischer system. A revised system formulated by the International Union of Pure and Applied Chemistry-International Union of Biochemistry (IUPAC-IUB) Joint Commission on Biochemical Nomenclature is appropriate for more complex needs.[104]

Traditional extraction methods for porphyrins have two steps: first, extraction into an acidified organic solvent, followed by a second or back extraction into aqueous acid. The initial extraction takes advantage of the fact that at pH 3 to 5 (near to their isoelectric point) porphyrins are less soluble in aqueous media and move into the organic phase. Coproporphyrin and protoporphyrin are readily extracted into diethyl ether, but the more highly carboxylated porphyrins (uroporphyrin and heptacarboxylate porphyrin) require the use of a more hydrophilic solvent, such as cyclohexanone or butanol. The back extraction induces porphyrin compounds to move back into the aqueous solution by decreasing the pH to less than 2. This pH shift causes the protonation of the pyrrolenine nitrogens and carboxylate groups, thereby reversing the solubility characteristics of porphyrins. Compounds such as heme and chlorophyll in which the pyrrole nitrogens are tightly bound to iron and magnesium, respectively, remain uncharged at low pH and trapped in the organic layer.

C_m, carboxymethyl (—CH_3COOH); C_{et}, carboxyethyl (—CH_2CH_2COOH); *Me*, methyl (—CH_3); *Et*, ethyl (—CH_2CH_3); *Vn*, vinyl (—$CH_2 = CH_2$).

HEME BIOSYNTHESIS

The complex tetrapyrrole ring structure of heme is built up in a stepwise fashion from the very simple precursors succinyl-CoA and glycine (Figure 32-2).[24] The pathway is present in all nucleated cells. From measurements of total bilirubin production,[4] it has been estimated that daily synthesis of heme in humans is 5 to 8 mmol/kg body weight. Of this, 70% to 80% occurs in the bone marrow and is used for hemoglobin synthesis. Approximately 15% is synthesized in the liver and is used to produce cytochrome P-450, mitochondrial cytochromes, and other hemoproteins. The pathway is compartmentalized, with some steps occurring in the mitochondrion and others in the cytoplasm. Little is known about the transport of intermediates across the mitochondrial membrane, and no transport defect has yet been reported in the porphyrias.

Enzymes of Heme Biosynthesis

The genes for all the enzymes of human heme biosynthesis have been characterized (Table 32-2), and the structures of 5-aminolevulinic acid dehydratase (ALAD), hydroxymethylbilane synthase (HMBS), uroporphyrinogen-III synthase (UROS), uroporphyrinogen decarboxylase (UROD), and ferrochelatase (FECH) have been determined by x-ray crystallography.[47,94,97,153,158]

5-Aminolevulinate Synthase (EC 2.3.1.37), ALAS

ALAS is the initial enzyme of the pathway and catalyzes the formation of ALA from succinyl-CoA and glycine. The enzyme is mitochondrial and requires pyridoxal phosphate as a cofactor, which forms a Schiff base with the amino group of glycine at the enzyme surface. The carbanion of the Schiff base displaces Co enzyme A from succinyl-CoA with the formation of α-amino-β-ketoadipic acid, which is then decarboxylated to ALA. The activity of ALAS is rate limiting as long as the catalytic capacities of other enzymes in the pathway are normal.

5-Aminolevulinic Acid Dehydratase (EC 4.2.1.24), ALAD

ALAD (also known as porphobilinogen synthase) is a cytoplasmic enzyme that catalyzes the formation of the monopyrrole porphobilinogen (PBG) from two molecules of ALA with elimination of two molecules of water. The enzyme requires zinc ions as a cofactor and reduced sulfhydryl groups at the active site and is therefore susceptible to inhibition by lead.

Hydroxymethylbilane Synthase (EC 2.5.1.61), HMBS

HMBS (also known as porphobilinogen [PBG] deaminase) is a cytoplasmic enzyme that catalyzes the formation of one molecule of the linear tetrapyrrole 1-hydroxymethylbilane (HMB; also known as preuroporphyrinogen) from four molecules of PBG with the release of four molecules of ammonia.[149] The former enzyme committee designation for HMBS was EC 4.3.1.8, but in 2003 the enzyme was redesignated as EC 2.5.1.61. The enzyme has two molecules of its own substrate: PBG, attached covalently to the apoenzyme as a prosthetic group.[138] The enzyme is susceptible to allosteric inhibition by intermediates further down the heme biosynthetic pathway, notably coproporphyrinogen-III and protoporphyrinogen-IX.[101]

Uroporphyrinogen-III Synthase (EC 4.2.1.75), UROS

UROS is a cytoplasmic enzyme that rearranges and cyclizes HMB to form uroporphyrinogen-III.[149] Each pyrrole ring of HMB contains a methylcarboxylate and an ethylcarboxylate substituent, which are in the same orientation. By the rotation of none, one, or two alternate or two adjacent pyrrole rings it is possible to arrive at four different isomers. Apart

TABLE 32-2 Human Enzymes and Genes of Heme Biosynthesis

Enzyme	Monomer Mol Wt (kDa)*†	Chromosomal Location of Gene	Gene Size (kb)	# Exons	Expression

*ALAD is a homooctamer, HMBS and UROS are monomers, all other enzymes are homodimers.
†Molecular weights for ALAS1, ALAS2, CPO, and FECH include presequences that are cleaved during mitochondrial import.

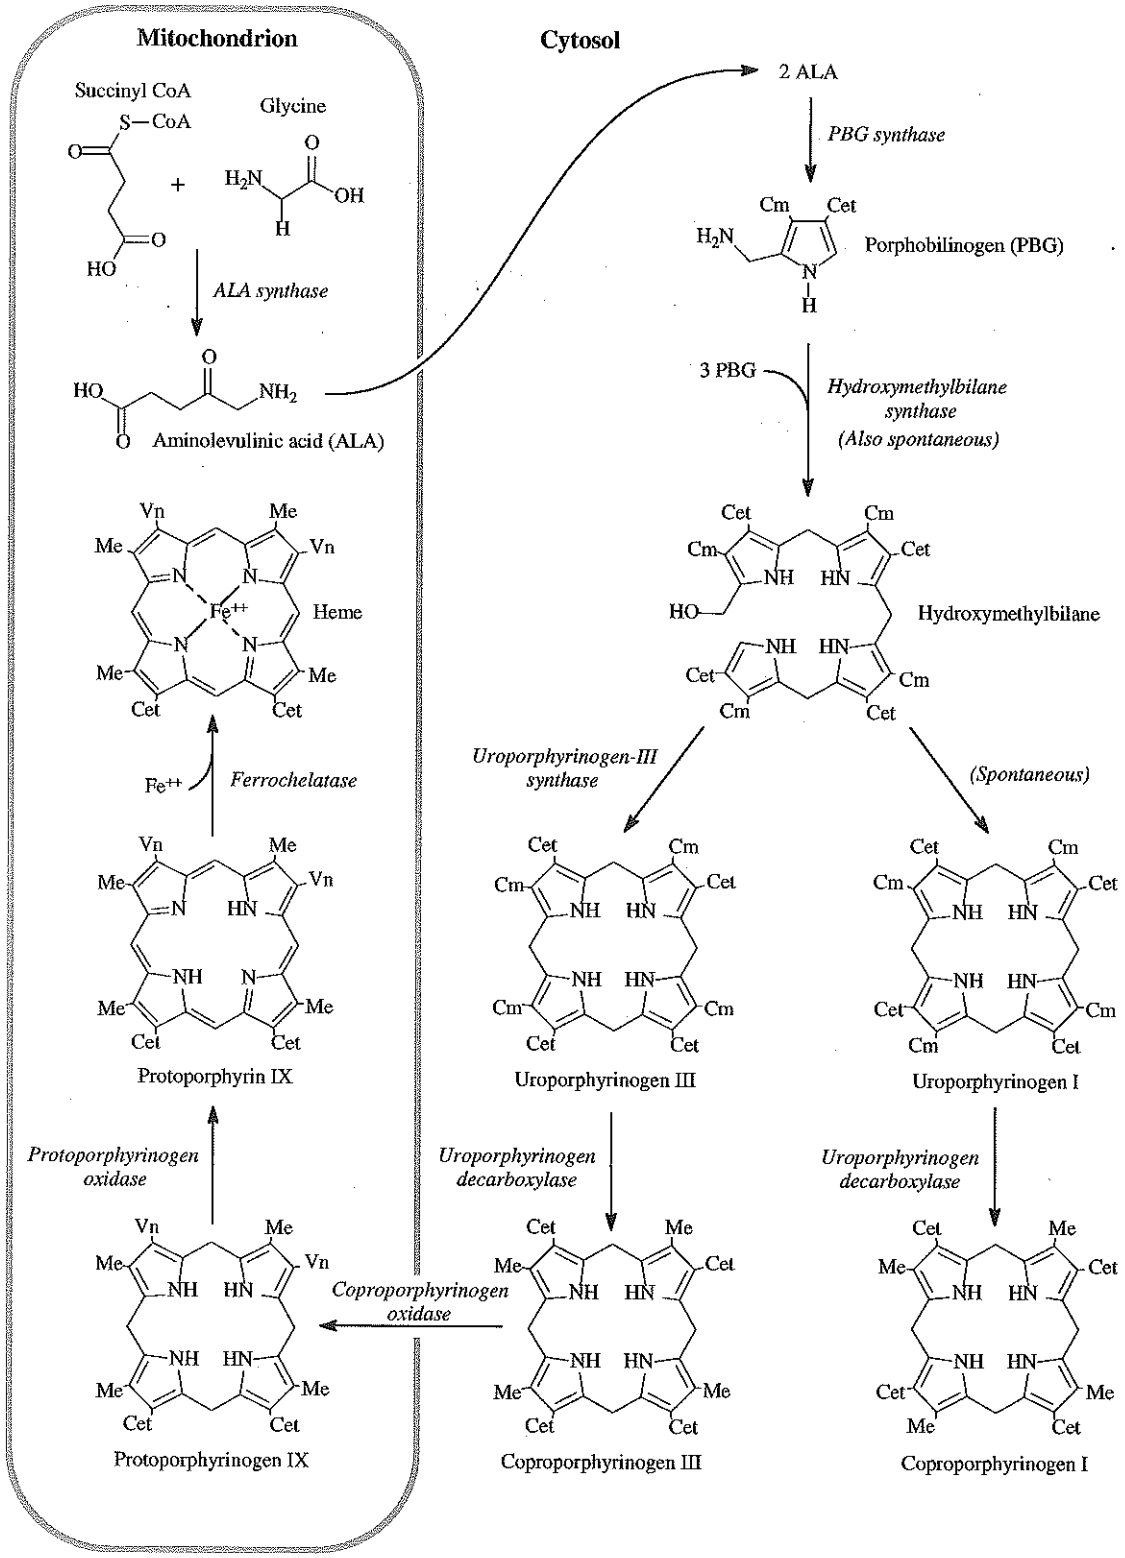

Figure 32-2 Biosynthetic pathway of porphyrins and heme. C_{et}, $—CH_2CH_2COOH$; C_m, $—CH_2COOH$; Me, $—CH_3$; Vn, $—CH=CH_2$.

from closing the ring structure, the enzyme rotates the D-ring via a spirane intermediate,[3] producing the type-III isomer—this is vital since only this isomer contributes to heme biosynthesis. HMB is unstable and in those porphyrias in which excess HMB accumulates, cyclization occurs nonenzymatically with the formation of the type-I isomer. Normally, only minimum amounts of uroporphyrinogen-I are formed.

Uroporphyrinogen Decarboxylase (EC 4.1.1.37), UROD

This is the last cytoplasmic enzyme in the pathway and catalyzes the decarboxylation of all four carboxymethyl groups to form the tetracarboxylic coproporphyrin. The enzyme will use both the I and III isomers of uroporphyrinogen as substrate. Decarboxylation commences on ring D and proceeds stepwise through rings A, B and C with formation of heptacarboxylate, hexacarboxylate, and pentacarboxylate intermediates at a single active site.[74] A UROD deficiency causes accumulation of these intermediates in addition to its substrate, uroporphyrinogen. At high substrate concentrations, decarboxylation occurs by a random mechanism.[95]

Coproporphyrinogen Oxidase (EC 1.3.3.3), CPO

CPO is situated in the intermembrane space of mitochondria and catalyzes the sequential oxidative decarboxylation of the 2- and 4-carboxyethyl groups to vinyl groups to produce the more lipophilic protoporphyrinogen-IX, with formation of a tricarboxylic intermediate, harderoporphyrinogen.[88] Oxygen is required as the oxidant. The enzyme requires sulfhydryl groups for activity, making it a target for inhibition by metals.[155] The enzyme is specific for the type-III isomer, so that metabolism of the I-series of porphyrins does not occur beyond coproporphyrinogen-I. The product of the enzyme differs from the substrate in that the replacement of two of the carboxyethyl groups by vinyl groups has introduced a third substituent into the molecule. Therefore the number of possible isomeric forms increases, and conventionally the numbering system changes so that the III isomer becomes the IX isomer. Because of increasing complexity, this Roman numeral designation is no longer recommended above IV.[104] In UROD-deficient states, one of the ethylcarboxylate groups of the accumulated pentacarboxylate porphyrinogen is decarboxylated by an unknown mechanism to form the isocoproporphyrin series of porphyrins.

Protoporphyrinogen Oxidase (EC 1.3.3.4), PPOX

PPOX is a flavoprotein located in the inner mitochondrial membrane and catalyzes the removal of six hydrogens (four from methylene bridges and two from ring nitrogens) to form protoporphyrin-IX. This involves a three-step, six-electron flavin adenine dinucleotide (FAD)–dependent oxidation that consumes molecular oxygen.[24] Nonenzymatic oxidation also occurs in vitro. However, under the oxygen tension in the cell, PPOX is essential for the oxidation to occur. The protoporphyrin produced is the only porphyrin that functions in the heme pathway. Other porphyrins are produced by nonenzymatic oxidation and represent porphyrinogens that have irreversibly escaped from the pathway.

Ferrochelatase (EC 4.99.1.1), FECH

FECH (also known as heme synthase) is an iron-sulfur protein[158] located in the inner mitochondrial membrane. This enzyme inserts ferrous iron into protoporphyrin to form heme. During this process, two hydrogens are displaced from the ring nitrogens. Other metals in the divalent state will also act as substrate,[85] yielding the corresponding chelate (e.g., incorporation of Zn^{2+} into protoporphyrin to yield zinc protoporphyrin). In iron-deficient states Zn^{2+} successfully competes with Fe^{2+} in developing red cells so that the concentration of zinc protoporphyrin in erythrocytes increases. Furthermore, other dicarboxylic porphyrins will also serve as substrates (e.g., mesoporphyrin).

EXCRETION OF HEME PRECURSORS

Normally, only minute amounts of heme precursors accumulate. The route of excretion largely depends on solubility. The porphyrin precursors ALA and PBG are water soluble and are excreted almost exclusively in urine. Uroporphyrinogen, with eight carboxylate groups, is readily water soluble and is also excreted via the kidney. The last intermediate of the pathway, protoporphyrin (and also protoporphyrinogen), which has only two carboxylate groups, is insoluble in water and is excreted in the feces via the biliary tract. The other porphyrins are of intermediate solubility and appear in both urine and feces. Coproporphyrinogen-I is taken up and excreted by the liver in preference to the III isomer so that coproporphyrinogen-I predominates in feces and coproporphyrinogen-III in urine. All porphyrinogens in the urine or feces are slowly oxidized to the corresponding porphyrins. Reference intervals for porphyrins and their precursors in urine, feces, and blood are given in Table 32-3.

Once in the gut, porphyrins are susceptible to modification by gut flora. The two vinyl groups of protoporphyrin are reduced to ethyl groups, hydrated to hydroxyethyl groups, or removed, giving rise to a variety of secondary porphyrins. Gut flora can also metabolize heme (whether of dietary heme, as components from cells sloughed off from the lining of the gut, or resulting from gastrointestinal bleeding) to produce a variety of dicarboxylic porphyrins.[6] Furthermore, some bacteria are capable of de novo synthesis of porphyrins.

REGULATION OF HEME BIOSYNTHESIS

Heme supply in all tissue is controlled by the activity of mitochondrial ALAS, the first enzyme of the pathway. There are two isoforms of ALAS. The ubiquitous isoform, ALAS1, is encoded by a gene on chromosome 3p21 and expressed in all tissue. Since it has a half-life of only about an hour, changes in its rate of synthesis produce short-term alterations in enzyme concentration and cellular ALAS activity. Synthesis of ALAS1 is under negative feedback control by

TABLE 32-3 Adult Reference Intervals

Specimen	Analyte	Reference interval

heme.[99] In the liver, but not most other tissue, ALAS1 is induced by a wide range of drugs and chemicals that induce microsomal cytochrome P-450 dependent oxidases (CYPs). This effect is probably mediated mainly by direct transcriptional activation by drug-responsive nuclear receptors[51] rather than being secondary to depletion of an intracellular regulatory heme pool as a consequence of use of heme for CYP assembly. Induction of ALAS1 is prevented by heme, which acts by destabilizing messenger ribonucleic acid (mRNA) for ALAS1, by blocking mitochondrial import of pre-ALAS1, and possibly by inhibiting transcription.[99]

The erythroid isoform, ALAS2, is encoded by a gene on chromosome Xq21-22 and is expressed only in erythroid cells. Its activity is regulated by two distinct mechanisms.[119] Transcription is enhanced during erythroid differentiation by the action of erythroid-specific transcription factors, and mRNA concentrations are regulated by iron. Iron deficiency in erythroid cells promotes specific binding of iron regulatory proteins to an iron-responsive element in the 5′ untranslated region (UTR) of ALAS2 mRNA with consequent inhibition of translation.

ABNORMALITIES OF PORPHYRIN METABOLISM

Abnormalities of porphyrin metabolism are caused by inherited defects in the genes of the biosynthetic pathway enzymes, diseases called the porphyrias, or by conditions (e.g., lead toxicity) that affect the enzymatic activity in subjects with normal heme synthesis genes.

The Porphyrias

The porphyrias are a group of metabolic disorders that result from partial deficiencies of the enzymes of heme biosynthesis[1] (Table 32-4). All are inherited in monogenic patterns, apart from some forms of porphyria cutanea tarda (PCT) and rare types of erythropoietic porphyria. Each type of porphyria is defined by the association of characteristic clinical features with a specific pattern of accumulation of heme precursors that reflects increased formation of substrates for the enzyme that is deficient in that type of porphyria (Table 32-5).

The porphyrias are characterized clinically by two main features: skin lesions on sun-exposed areas and acute neurovisceral attacks, typically comprising abdominal pain, peripheral neuropathy, and mental disturbance. The skin lesions are caused by porphyrin-catalyzed photodamage of which singlet oxygen is the main mediator.[118] Acute attacks are associated with increased formation of ALA from induced activity of hepatic ALAS1 and partial hepatic heme deficiency, often in response to induction of hepatic cytochrome P450s (CYPs) by drugs and other factors. The relationship of these biochemical changes to the neuronal dysfunction that underlines all the clinical features of the acute attack is uncertain.[105] ALA may act as a neurotoxin; heme deficiency in the liver may interfere with the synthesis of neurotransmitters, the action of heme-dependent enzymes in the nervous system may be impaired, or one or more of these effects may act together.

In Table 32-4 the porphyrias are divided into the acute porphyrias, in which acute neurovisceral attacks occur, and the nonacute porphyrias. Other classifications include division into hepatic (acute intermittent porphyria [AIP], hereditary coproporphyria [HCP], variegate porphyria [VP], and PCT) and erythropoietic (congenital erythropoietic porphyria [CEP], erythropoietic protoporphyria [EPP]) porphyrias according to the main site of overproduction of

TABLE 32-4 The Main Types of Human Porphyria

Disorder	Defective Enzyme	Prevalence*	Neurovisceral Crises	Skin Lesions	Inheritance
Acute Porphyrias					
ALA dehydratase deficiency porphyria (ADP)	ALAD	–	+	–	AR
AIP	HMBS	1-2:100,000	+	–	AD

Nonacute Porphyrias					
CEP	UROS	1:10^6	–	0.001[‡]	AR
PCT	UROD	1:25,000	–	+[‡]	Complex
EPP	FECH	1:130,000	–	+[§]	AR (20% AD) Complex (mainly AD)

*Estimated prevalence of clinically overt disease in the United Kingdom.
[†]Skin lesions and neurovisceral crises may occur alone or together.
[‡]Fragile skin, bullae.
[§]Acute photosensitivity without fragile skin, bullae.
AR, Autosomal recessive; *AD,* autosomal dominant.

TABLE 32-5 The Porphyrias: Patterns of Overproduction of Heme Precursors During Clinically Overt Phase of Disease

Porphyria	Urine PBG/ALA	Urine Porphyrins	Fecal Porphyrins	Erythrocyte Porphyrins	Plasma Fluorescence Emission Peak
ADP	ALA	Copro III	Not increased	Zn-proto	—
AIP	PBG > ALA	Mainly uroporphyrin from PBG	Normal, or slight increase in Copro, Proto[a]	Not increased	615-620 nm[b]
CEP	Not increased	Uro I, Copro I	Copro I	Zn-proto, Proto, Copro I, Uro I	615-620 nm
PCT	Not increased	Uro, Hepta[c]	Isocopro, Hepta[c]	Not increased	615-620 nm
HCP	PBG > ALA[d]	Copro III, uroporphyrin from PBG	Copro III	Not increased	615-620 nm[b]
VP	PBG > ALA[d]	Copro III, uroporphyrin from PBG	Proto IX > Copro III, X-porphyrin	Not increased	624-628 nm
EPP	Not increased	Not increased	+/–Proto[e]	Proto	626-634 nm[f]

[a]Total porphyrin may be increased because of presence of excess uroporphyrin.[127]
[b]Not always increased during acute attack.
[c]Other methylcarboxylate substituted porphyrins are increased to a smaller extent; uroporphyrin is a mixture of type I and III isomers; heptacarboxylate porphyrin is mainly type III.
[d]PBG and ALA may be normal when only skin lesions are present.
[e]Not increased in about 40% of patients.
[f]Protoporphyrin bound to globin (if there is hemolysis in the sample) has a peak at 626-628 nm.

heme precursors, or into cutaneous and acute porphyrias, but both of these classifications make some porphyrias difficult to place.

Acute Porphyrias

The acute porphyrias include ALA dehydratase deficiency porphyria (ADP), AIP, VP, and HCP. These disorders are autosomal dominant except for ADP, which is autosomal recessive.

Biochemistry and Molecular Genetics

The inherited defect in each of the autosomal dominant acute porphyrias (AIP, VP, and HCP, Table 32-4) is a mutation leading to complete or near complete inactivation of one of the pairs of allelic genes that encode the enzyme whose partial deficiency causes the disorder. Enzyme activities are therefore half of normal in all tissue in which they are expressed, reflecting the activity of the normal gene *trans* to the mutant allele. Heme supply is maintained at normal or near normal levels by up regulation of ALAS, with a consequent increase in the substrate concentration for the defective enzyme. These compensatory changes vary between tissues, being most prominent in the liver and undetectable in most other organs, and between individuals. Thus in all autosomal dominant acute porphyrias, some individuals show no evidence of overproduction of heme precursors, and others have biochemically manifest disease with or without clinical symptoms.

Low clinical penetrance is a prominent feature of all the autosomal dominant acute porphyrias. Family studies indicate that about 80% of affected individuals are asymptomatic throughout life. Surveys of blood donors suggest that the AIP gene may be present in as many as 1 in 1500 of the population.[111] For all three disorders, the gene frequency is sufficiently high for rare "homozygous" variants of AIP, HCP, or VP to occur in individuals who are homozygotes or compound heterozygotes for disease-specific mutations[41,89] and for the same person to have two separate types of porphyria.

All the autosomal dominant acute porphyrias show extensive allelic heterogeneity.[38,44,63,89,103] More than 200 disease-specific mutations have been identified in AIP and more than 120 in VP (Human Gene Mutation Database: www.hgmd.org). About 3% of families with AIP have HMBS mutations that impair expression of the ubiquitous isoform and therefore do not decrease activity in erythroid cells. All other mutations in the autosomal dominant acute porphyrias affect all tissue. Most are restricted to one or a few families, but founder mutations are present in some populations and explain the high frequency of VP in South Africans of Dutch descent and of AIP in Sweden.[42,89]

About 25% of patients with overt acute porphyria have no family history of the disease. Such sporadic presentation is a reflection of the high prevalence of mutations in the population; acute porphyria caused by de novo mutation is uncommon.

Unlike the other acute porphyrias, ADP is an autosomal recessive disorder. Patients are compound heterozygotes or homozygotes for a range of mutations in the ALAD gene. The prevalence of heterozygous carriers may be as high as 2% in some populations.[96]

Clinical Features

The life-threatening, acute neurovisceral attacks that occur in AIP, VP, and HCP are clinically identical.[42,64,89] Acute attacks are more common in women, usually occurring first between the ages of 15 and 40, and are very rare before puberty. Their main clinical features are summarized in Table 32-6. The clinical features of ADP, which has been reported in only six families, are similar but may start in childhood.[132]

Acute attacks almost always start with abdominal pain that rapidly becomes very severe but is not accompanied by other signs of an acute surgical condition. Pain may also be present in the back and thighs and may occasionally be most severe in these regions. Signs of autonomic neuropathy, such as vomiting, constipation, tachycardia, and hypertension, are frequent. When convulsions occur, they are often caused by hyponatremia. Pain may dissipate within a few days, but in severe cases a predominant motor neuropathy develops that may progress to flaccid quadriparesis. Persistent pain and vomiting may lead to weight loss and malnutrition. The acute phase may be accompanied by mental confusion with abrupt changes in mood, hallucinations, and other psychotic features. However, these mental disturbances disappear with remission. Persistent psychiatric illness is not a feature of the acute porphyrias, though mild anxiety or depression may be present in some patients.[106] Abdominal pain usually resolves within 2 weeks, but recovery from neuropathy may take many months and is not always complete. Most patients have one or a few attacks followed by complete recovery and prolonged remission. About 5% have repeated acute attacks, which in women may be premenstrual.

TABLE 32-6 Clinical Features of an Acute Neurovisceral Attack of Porphyria

Symptom/Sign	Percent of Acute Attacks
Abdominal pain	97
Nonabdominal pain	25
Vomiting	85
Constipation	46
Psychological symptoms	8
Convulsions	5
Muscle weakness	8
Sensory loss	2
Hypertension (diastolic > 85 mm Hg)	64
Tachycardia (> 80/min)	65
Hyponatremia (< 135 nmol/L)	37

Data from Elder GH, Hift RJ. Treatment of acute porphyria. Hosp Med 2001;62:422-8.

Precipitating factors can be identified in about two thirds of patients who present with acute attacks. The most important are drugs, alcohol—especially binge drinking—the menstrual cycle, pregnancy, calorie restriction, infection, and stress. Drugs known to provoke acute attacks include barbiturates, sulfonamides, progestogens, and most anticonvulsants, but many others have been implicated in the precipitation of acute attacks.[1,72,89] Many of these precipitating factors induce hepatic CYPs.

Skin lesions similar to those of PCT and other bullous porphyrias are present in about 80% of patients with clinically manifest VP (Table 32-4). About 60% of patients with this condition present with skin lesions alone.[152] The skin is less commonly affected in HCP; skin lesions without an acute attack are uncommon and usually provoked by intercurrent cholestasis.[102]

Long-term complications of acute porphyria include chronic renal failure, hypertension, and hepatocellular carcinoma.[1,89]

Treatment

As soon as an attack of acute porphyria is suspected as the cause of illness, drugs and other potential provoking agents should be withdrawn and supportive treatment started using drugs that are known to be safe.[43] Opiates are usually required to control pain. Addition of chlorpromazine or promazine may help to reduce the requirement for analgesics. Patients are prone to severe hyponatremia, and careful administration of any intravenous fluids, with avoidance of hypotonic solutions, is essential. If hyponatremia develops, it should be corrected slowly because patients with acute porphyria are particularly susceptible to cerebral edema and osmotic demyelination. Adequate caloric intake must be maintained, preferably by giving carbohydrate-rich supplements orally or if necessary via a nasogastric tube. When vomiting prevents enteral administration, 100 g of dextrose per day given intravenously as a 5% solution in normal saline should suffice.

Unless the attack is mild and clearly resolving, specific treatment with intravenous heme should be started as soon as the diagnosis has been established.[43,89,109] This treatment increases the concentration of heme in the liver, thus decreasing the activity of ALAS1 and the formation of ALA and PBG. The effect of treatment may be monitored by measuring these metabolites, but this is not essential because clinical improvement is the required end point. Heme administration will not reverse an established neuropathy. If heme preparations are not available, hepatic ALA synthase activity can be decreased by carbohydrate loading,[13] but this treatment is less effective than intravenous heme and more difficult to administer.

Repeated attacks are difficult to control. Cyclical premenstrual attacks in women may be prevented by suppression of ovulation with gonadorelin analogues,[1,43] but most patients require repeated courses of intravenous heme. In one patient with AIP, orthotopic liver transplantation led to immediate and prolonged remission with restoration of PBG excretion to normal.[141]

Management of Families

Diagnosis of autosomal dominant acute porphyria should be followed by investigation of the patient's family to identify affected, often asymptomatic, relatives so that they can be advised to avoid factors known to provoke potentially fatal acute attacks. Presymptomatic diagnosis also has the benefit that specific treatment can be started promptly if an attack does develop without delay while a diagnosis is sought. Though attacks are very rare before puberty, children should be tested at as young an age as is practicable to ensure that their status is known by the time they reach puberty and to enable the very low risk for affected children to be further reduced. Counseling to reduce the risk of an acute attack should include comprehensive information about the disease, including specific advice to guide selection of safe drugs, and provision of jewelry or some other means to identify the individual as having an acute porphyria.

Nonacute Porphyrias

The nonacute porphyrias include PCT, CEP, and EPP.

Porphyria Cutanea Tarda

PCT is by far the most common porphyria.[38,41] The annual incidence of new cases in the United Kingdom is between 2 and 5 per million of the population.[41] The disease occurs at all ages in both sexes with onset usually during the fifth and sixth decades.

Clinical Features

Lesions on sun-exposed skin, particularly the backs of the hands, forearm, and face, are present in all patients. These lesions are identical to those seen in the other bullous porphyrias (Table 32-4). Increased mechanical fragility of the skin, with trivial trauma leading to erosions, is present in virtually all patients. Subepidermal bullae, hypertrichosis of the face, and patchy pigmentation are also common. Erosions and bullae heal slowly to leave atrophic scars, milia, and depigmented areas. Patchy or diffuse sclerodermatous changes are less common and, unlike the other skin lesions, may affect areas of the trunk that are not exposed to sun.

The skin lesions are often the first sign of underlying liver cell damage. Clinically, overt liver disease is uncommon, but minor alterations in biochemical tests of liver function are present in more than 50% of patients. Needle biopsy of the liver reveals hepatic siderosis in most patients, usually accompanied by minor histopathological abnormalities: mild fatty infiltration, focal necrosis of hepatocytes, and inflammation of portal tracts. Cirrhosis is unusual, being present in less than 15% of patients, but carries a high risk of hepatocellular carcinoma.

The combination of skin lesions with liver damage is strongly associated with alcohol abuse, estrogens, infection

with hepatotropic viruses, particularly hepatitis C (HCV), and mutations in the hemochromatosis (HFE) gene.[14,38] Hepatic iron overload and at least one of the other associated factors are present in almost all patients. Between 8% and 79% of patients have antibodies to HCV, the prevalence being highest in the United States and southern Europe and lowest in Western Europe. About 20% of patients of Northern European descent are homozygous for the C282Y mutation in the HFE gene, but in spite of having the genotype of genetic hemochromatosis, very few show clinical evidence of iron overload. However, increased serum ferritin concentrations and other biochemical indicators of iron overload are common in PCT irrespective of the HFE genotype, suggesting that the origin of hepatic iron overload is multifactorial. PCT may also occur in association with other disorders, notably chronic renal failure, systemic lupus erythematosus, and hematological malignancies. In addition, rare cases of a PCT-like syndrome resulting from production of porphyrins by primary hepatic tumors have been described.[112]

Pathogenesis and Molecular Genetics

PCT results from a decrease in activity of UROD in the liver, which leads to overproduction of uroporphyrin and other carboxymethyl-substituted porphyrinogens. These autooxidize to porphyrins, which accumulate in the liver and skin where they act as photosensitizers and are excreted in urine and bile. Two main types of PCT can be identified by measurement of UROD activity in liver and extrahepatic tissue, and analysis of the UROD gene. About 80% of patients have the sporadic (type-I) form of PCT in which the enzyme defect is restricted to the liver, and the UROD gene appears to be normal. Typically, there is no family history of PCT, but rare cases are clustered in families (type-III PCT). The rest have familial (type-II) PCT. In this form, mutation of one UROD gene leads to half of normal UROD activity in all tissue, which is inherited in an autosomal dominant manner.[113] As with the other autosomal dominant porphyrias, clinical penetration of familial PCT is low and there is considerable allelic heterogeneity, with each of the more than 50 mutations described being present in only one or a few families. A rare variant of familial PCT, hepatoerythropoietic porphyria (HEP), in which UROD mutations, some of which have also been found in familial PCT, are present on both alleles, has been described.[38,41] PCT may also be caused by exposure to certain polyhalogenated aromatic hydrocarbons, such as hexachlorobenzene[23] and 2,3,7,8-tetrachlorodibenzo-p-dioxin.[38]

In families with familial PCT, half-normal enzyme activity is not by itself sufficient to cause clinically overt disease. Further inactivation of UROD in the liver seems to be required, and the process responsible for this inactivation appears also to be responsible for inactivation of hepatic UROD in sporadic PCT and in toxic PCT caused by chemicals.[38,44] The inactivation process decreases catalytic activity without impairing immunoreactivity, is iron dependent, and is reversible. Current evidence from experimental models of PCT suggests that UROD is inactivated by an inhibitor that is produced by iron-dependent oxidation of a substrate of the UROD reaction, possibly mediated by hepatic CYPs, particularly CYP1A2. The putative inhibitor has not yet been identified.

Treatment

In addition to protection of the skin from sunlight, there are two specific treatments for PCT: depletion of hepatic iron stores by repeated phlebotomy or other means, and low-dose oral chloroquine.[131] In patients with chronic renal failure and PCT, hepatic iron stores can be decreased by erythropoietin with or without phlebotomy.

Congenital Erythropoietic Porphyria

CEP is the least common but most severe of the cutaneous porphyrias.[53,147] The prevalence is less than one per million in the United Kingdom. This disorder is also known as Günther disease.

Clinical Features

The clinical features range in severity from hydrops fetalis with death in utero—through the onset in infancy of severe skin lesions with transfusion-dependent hemolytic anemia—to mild skin lesions, resembling PCT, that do not start until adult life. Late-onset cases may also develop in association with hematological malignancy, particularly myelodysplasia.[80]

Most patients present in early infancy. Blisters on skin exposed to the sun or other sources of ultraviolet A (UVA) radiation, and reddish-brown staining of diapers by urinary porphyrins, are common early signs. The skin lesions resemble those of PCT but are more severe and persistent throughout life. With age, progressive scarring, particularly if erosions become infected, and atrophic changes lead to photomutilation with erosions of the terminal phalanges; destruction of ears, nose, and eyelids; and alopecia. Accumulation of porphyrin in bone is visible as erythrodontia—brownish-red teeth that fluoresce in UVA light. The skin changes are usually accompanied by hemolytic anemia and splenomegaly. Hemolysis may be fully compensated or mild but, in some patients, anemia is severe enough to require repeated transfusion.

Molecular Pathology

CEP is an autosomal recessive disease. Patients are homoallelic or heteroallelic for mutations in the UROS gene that decrease UROS activity (Table 32-2). Decreased UROS activity leads to massive overproduction of uroporphyrinogen-I and other isomer-I series of porphyrins, mainly in the bone marrow. Porphyrins accumulate in erythrocytes, and their precursors are released into the plasma as these cells die.

Most patients are heteroallelic unless their parents are consanguineous. More than 30 separate mutations have been identified; C73R is at a mutation "hot spot" in the gene and has been found on 34% of alleles investigated to date. Geno-

type and/or phenotype comparisons show some correlation.[33] Patients who are homozygous for C73R have particularly severe disease; in compound heterozygotes, the effect of C73R is modified by the nature of the mutation on the other allele. Other mutations are associated with mild disease.

Treatment

Protection against sunlight and prevention of skin infections are essential. Sunscreen ointments may occasionally provide some benefit, but physical avoidance of UVA radiation is usually necessary. Hypertransfusion and activated charcoal to decrease the enterohepatic circulation of porphyrin, hydroxyurea, intravenous heme, and antioxidant preparations have also been used to suppress erythropoiesis and porphyrin formation or to ameliorate the effects of porphyrin accumulation but none has been shown to have a reliable, long-term effect.[33,53,147] Hemolytic anemia may require repeated transfusion and infusion of deferoxamine to prevent iron overload.

At present the only curative treatment is allogeneic bone marrow transplantation. Gene therapy by introduction of a normal UROS gene into the patient's hematopoietic stem cells remains under development.[147]

Erythropoietic Protoporphyria

EPP is characterized by life-long acute photosensitivity caused by accumulation of protoporphyrin-IX in the skin.[22,146] The absence of fragile skin, subepidermal bullae, and hypertrichosis distinguishes it clinically from all other cutaneous porphyrias.

Clinical Features

Patients present with acute photosensitivity, normally between the ages of 1 and 6, and both sexes are equally affected. Once a child within an EPP family reaches the age of 14, the risk of developing acute photosensitivity becomes very low. Onset during adult life is very rare; most cases have been associated with myelodysplasia.[2]

Exposure to sun is followed, usually within 5 to 30 minutes, by an intensely painful, burning, prickling, itching sensation in the skin, most frequently on the face and backs of the hands. Symptoms persist for several hours or occasionally days and are not relieved by shielding the skin from light. Patients characteristically seek relief by plunging their hands into water or covering their skin with wet towels. Young children may become very distressed by the pain. The skin may appear normal throughout although there is often erythema, which may be followed by edematous swelling with crusting. These changes usually subside within a few hours so that by the time the child reaches the physician there is nothing to be seen, and the episode may be dismissed as severe sunburn. Subsequent exposure to sunlight provokes a similar reaction. Recurrent episodes lead to chronic skin changes that are often minor and hard to detect. Typical lesions are shallow linear scars over the bridge of the nose and elsewhere on the face, and the skin may become thickened and waxy, especially over the knuckles. Symptoms tend to be more severe during spring and summer and may improve during pregnancy.

The most severe complication of EPP is progressive hepatic failure that is caused by accumulation of protoporphyrin in the liver.[22,146] About 20% of patients have abnormal biochemical tests of liver function, particularly increased aspartate aminotransferase, but only 2% to 5% of patients develop liver failure. EPP may also increase the risk of cholelithiasis, the formation of gallstones being promoted by high concentrations of protoporphyrin in the bile.

Clinically significant anemia is unusual. About 25% of patients have a mild, hypochromic, microcytic anemia, which may be accompanied by sideroblastic changes in erythroid precursor cells.

Molecular Pathology and Genetics

The primary biochemical abnormality in EPP is decreased *FECH* activity. Although this decrease is present in all tissue, the excess protoporphyrin is formed mainly in erythroid cells. Accumulation of protoporphyrin in the liver is the result of failure of the liver to excrete the increased load it receives from release of protoporphyrin from erythrocytes and their immediate precursors.

The mode of inheritance of EPP is complex but has recently been clarified by enzymatic and molecular studies of families.[63] Molecular analysis has identified more than 60 disabling mutations of the *FECH* gene that are inherited in EPP families in an autosomal dominant pattern. Within these families, *FECH* activities in patients with overt disease are lower than the half-normal activities in their asymptomatic relatives with the same mutation. Thus a decrease in *FECH* activity to less than 50% of normal appears to be essential for development of sufficient overproduction of protoporphyrin to produce symptoms. In most families, this further decrease is produced by inheritance of a low expression *FECH* allele *trans* to the severe mutation.[63] The low expression allele is a polymorphic *FECH* variant present in about 10% of the Western European population. Substitution of a T nucleotide by a C nucleotide at a polymorphic site in intron 3 (IVS3-48C/T) enhances use of an alternative splice site, leading to increased formation of an unstable, untranslated mRNA and reduction of *FECH* expression by about 25%. This pattern of inheritance has been described as autosomal dominant with modulation by expression of the wild type of FECH allele.[63] Uncommon autosomal recessive cases of EPP have also been reported.[22]

At present, genetic analysis does not enable patients at risk from liver disease to be identified with certainty. Patients with null mutations or autosomal recessive disease may be at greater risk than those with missense mutations *trans* to a low expression allele.[107]

Treatment

Acute photosensitivity can be controlled by avoidance of sunlight, suitable clothing, and reflectant sunscreens, if these

are cosmetically acceptable. Some patients are helped by production of a photoprotectant tan by measures such as narrowband ultraviolet B (UVB) phototherapy or dihydroxyacetone ointment. Oral β-carotene, which acts as a singlet oxygen quencher, is effective in some patients. Doses should be sufficient to maintain a plasma concentration of 6 to 8 μg/L.[146]

At present there is no reliable method for predicting liver failure in EPP. All patients should have at least annual biochemical tests of liver function. Persistent abnormalities should be investigated by liver biopsy and further treatment considered if even mild hepatocellular necrosis and fibrosis are present. Once liver failure develops, liver transplantation becomes the only treatment but protoporphyrin may reaccumulate in the transplanted liver.[70]

Abnormalities of Porphyrin Metabolism Not Caused by Porphyria

Abnormalities of porphyrin metabolism, excretion, or both may occur in the absence of porphyria caused by a number of other diseases that need to be considered when interpreting data from patients in whom porphyria is suspected.[9,45,69]

Lead Toxicity

Lead exposure increases urinary ALA and coproporphyrin-III excretion and causes accumulation of Zn-protoporphyrin in erythrocytes. The definitive test for lead toxicity is measurement of blood lead, but occasionally lead exposure is responsible for porphyria-like symptoms and may be an unexpected finding when investigating patients for suspected porphyria.[79]

Increased ALA excretion is secondary to inhibition of ALAD caused by lead displacing zinc at its catalytic center. Two isoenzymes (ALAD1 and ALAD2) are produced from the ALAD gene by alternative splicing activated by two nontranslated codominant alleles 1 and 2.[78] The ALAD2 isoenzyme is more electronegatively charged than ALAD1 so that its affinity for lead is higher.[151] As a consequence, individuals with the ALAD2 genotype are more susceptible to lead toxicity.[140] Furthermore, individuals who are heterozygous for ALAD deficiency appear to be at increased risk from lead exposure.[37]

Lead also leads to the increased excretion of coproporphyrin-III in urine. CPO requires sulfhydryl groups for activity and so is potentially a target for inhibition by lead. The increased levels of red cell zinc-protoporphyrin (ZPP) associated with lead exposure are probably not caused by inhibition of *FECH* because inhibition of this enzyme requires higher lead concentrations than those usually encountered following lead exposure. The current view is that lead exposure creates an intracellular iron deficiency (perhaps by affecting iron transport into the cell or inhibition of iron reductase) so that zinc replaces iron as a substrate for *FECH*.[84] Once formed, erythrocyte ZPP remains elevated for the life of the red cell. Since the half-life of an erythrocyte is longer than that of blood lead, monitoring of lead workers requires both whole-blood lead and ZPP testing. ZPP measurement also has the advantage that there is no interference from lead contamination via the skin when the blood sample is collected, especially if a finger-prick sample is used.

Other Toxic Exposures

Secondary coproporphyrinuria has also been described because of the toxic effects of alcohol,[139] arsenic,[54] and other heavy metals.[156]

Hereditary Tyrosinemia Type-I

Succinylacetone, which accumulates in this disease, has a structural resemblance to ALA and is therefore a competitive inhibitor of ALAD.[134] Consequently, its substrate ALA accumulates and excess amounts are excreted in urine. Patients with hereditary tyrosinemia suffer neurological crises very similar to attacks of acute porphyria.[120] They can be treated with heme infusions.[121]

Renal Disorders

Impaired glomerular function reduces the clearance of those water-soluble porphyrins normally excreted in the urine. Furthermore, these porphyrins are poorly cleared by dialysis and, as a consequence, plasma porphyrins are raised in end-stage renal failure.[48]

Hepatobiliary Disorders

In obstructive jaundice, cholestatic jaundice, hepatitis, and cirrhosis there is an increased excretion of predominantly coproporphyrin-I, because liver disease causes a diversion of the secretion of coproporphyrin-I from the biliary to the renal route.[36,124]

In the Dubin-Johnson syndrome there is increased urinary excretion of coproporphyrin-I and a reduced excretion of coproporphyrin-III.[50,82] In Rotor's syndrome, urinary excretion of coproporphyrin-I is increased with normal coproporphyrin-III excretion,[50,154] and in Gilbert's disease there is increased urinary excretion of both isomers.

Hematological Disorders

In iron deficiency anemia, zinc acts as an alternative substrate for FECH, leading to increased ZPP. Increased red cell protoporphyrin (mostly ZPP) may also occur in sideroblastic, megaloblastic, and hemolytic anemias.[100]

Diet, Bacteria, and Gastrointestinal Bleeding

The dicarboxylic porphyrin fraction of feces contains protoporphyrin and other dicarboxylic porphyrins derived from it by bacterial reduction or removal of vinyl side groups. Additional protoporphyrin and other dicarboxylic porphyrins may be formed by the action of gut flora on heme-containing proteins derived from the diet or gastrointestinal hemorrhage.[6,126] Even minor gastrointestinal hemorrhage, particularly if occurring high in the gut, which may not give rise to a positive occult blood test, can markedly increase the

concentration of dicarboxylic porphyrins in feces.[142] Confusion with EPP may occur when associated iron deficiency increases erythrocyte total porphyrin and when skin lesions from some other cause are present, or with VP when coexisting liver disease causes coproporphyrinuria. Porphyria can be excluded when no porphyrin fluorescence is detectable on fluorescence emission spectroscopy of plasma. Porphyrins may also come directly from the diet and there is one report of consumption of brewer's yeast producing a fecal porphyrin profile indistinguishable from VP.[91]

Pseudoporphyria

The term "pseudoporphyria" was originally applied to patients with PCT-like skin lesions in whom no abnormality of accumulation or excretion of porphyrins could be demonstrated.[65,67] Many drugs are potent photosensitizers and may produce porphyria-like lesions.[65] Plasma porphyrin concentrations are often raised in dialysis patients without porphyria because of impaired excretion of these molecules and inefficient clearance by dialysis.[48] Even in the absence of biochemical evidence of porphyria, dermatological problems commonly affect dialysis patients and often share common features of PCT (melanosis, actinic elastosis, fragility, and bullae).[59,137] The levels of plasma porphyrin seen in dialysis patients are often much higher than normal but rarely approach those found in patients with active skin lesions caused by PCT.[60] Nevertheless, the term "dialysis porphyria" has been coined for these patients even though it is unlikely that raised porphyrins are responsible for the skin lesions. Genuine PCT may occur in dialysis patients, and some of the cases of dialysis porphyria in the literature have not been adequately investigated to exclude PCT. These patients are often anuric, and without the benefit of urinary analysis, careful evaluation of plasma and fecal porphyrins[60] is necessary to distinguish pseudoporphyria from PCT and acute porphyrias in which skin lesions may occur.

LABORATORY DIAGNOSIS OF PORPHYRIA

A number of clinical situations exist that benefit from laboratory testing for heme precursors. These include patients with symptoms of acute porphyria, typical cutaneous lesions, and relatives of patients known to have porphyria.

Patients With Symptoms of Porphyria

The clinical features of the porphyrias are insufficiently specific to enable their diagnosis without laboratory investigation. In patients with current symptoms caused by porphyria, it is always possible to demonstrate excessive production of heme precursors. Diagnosis depends on demonstrating specific patterns of overproduction of heme precursors (Table 32-5) and is usually straightforward provided appropriate specimens are examined for the relevant intermediates using adequately sensitive techniques.[11,29,45,144] Acute attacks of porphyria are always associated with excess excretion of PBG, ALA, or both. Patients having cutaneous symptoms caused by porphyria always have an excessive production of porphyrins. DNA and enzyme studies give no information about disease activity, are rarely necessary to confirm the diagnosis in clinically overt porphyria, and are mainly of use for family studies.

Patients With Acute Neurovisceral Symptoms

Three strategies exist when testing patients with acute neurovisceral symptoms that depend on the clinical setting: (1) investigating the acute attack, (2) diagnosing the cause, and (3) investigating possible acute porphyria when the patient is in remission.

Investigation During a Suspected Acute Attack

The one essential investigation in patients with suspected acute porphyria is an adequately sensitive test for excess urinary PBG.[8,29] Failure to correctly diagnose an attack of acute porphyria not only delays appropriate life-saving treatment but may result in the patient being subjected to the risk of unnecessary surgery or administration of porphyrinogenic drugs, which may further aggravate the attack with potentially fatal consequences. On the other hand, a false diagnosis of porphyria may be just as serious by delaying vital surgery or other treatment and may also lead to analgesic (including opiate) misuse and dependency.

Measurement of urinary total porphyrin by itself is unhelpful and may be misleading. Concentrations are usually increased when PBG is present in excess, owing to in vitro polymerization of PBG to uroporphyrin. But increases in hepatobiliary disease, alcohol abuse, and other disorders are common.[69,100] During an attack, PBG excretion is grossly elevated, and the increase is usually in excess of 10 times the upper reference limit. Normal PBG, at a time when symptoms are present, excludes all acute porphyrias, except the very rare ADP, as their cause. In AIP, PBG usually remains elevated for weeks or even months after an attack. However, in VP or HCP, PBG may rapidly return to normal (sometimes within days) once the attack starts to resolve. Therefore if a suspected attack is entering remission or if clinical suspicion of acute porphyria persists, analysis of fecal and plasma porphyrins, with measurement of ALA if these are normal, is advisable even if PBG excretion is normal. Increased urinary PBG requires careful evaluation, since although the patient clearly has an acute porphyria, the disease may not be the cause of current symptoms. Some patients with AIP have very high rates of PBG excretion in the absence of symptoms, and there is poor correlation between urinary PBG and symptoms, with no "threshold" above which symptoms appear. PBG excretion increases during an acute attack, but detection of this change requires information about the patient's baseline excretion. Even though a high urinary PBG excretion increases the likelihood that porphyria is responsible for symptoms, the final diagnosis must always be made on clinical grounds.

If increased urinary PBG was found by a qualitative and/or semiquantitative screening test, then this finding

must be confirmed by a specific, quantitative method to eliminate the possibility of a false-positive test result.[98] This is best done on the original urine specimen (ideally stored frozen) since by the time a repeat is obtained, PBG may have returned to normal.

Testing for ALA is often performed along with PBG. Both are typically elevated in the acute porphyrias, although ALA is increased to a lesser extent. Inclusion of ALA allows lead poisoning and ADP to be detected, but the risk of missing these conditions is very low if total urinary porphyrin is measured in addition to PBG. Furthermore, measurement of ALA is more susceptible to interference.[81]

Differentiation Between the Acute Porphyrias

The management of the attack is the same regardless of the type of porphyria, so further investigation is not a matter of urgency. Differentiation between the acute porphyrias is essential for the selection of appropriate tests to use for family studies; the absence of skin lesions does not exclude VP or HCP (Table 32-4). If total fecal porphyrin is normal, then VP and HCP are excluded and the patient must have AIP. Assay of red cell HMBS activity is not essential and may mislead. If total fecal porphyrin is raised, porphyrins should be fractionated by a high-performance liquid chromatography (HPLC) technique capable of resolving coproporphyrin isomers.[90] In HCP, coproporphyrin-III is grossly elevated and protoporphyrin-IX minimally raised or normal. In VP, protoporphyrin-IX (and other dicarboxylate porphyrins) are raised, and there is a smaller increase in coproporphyrin (with the type-III isomer predominating) (Table 32-5). It is important to remember that protoporphyrin-IX and other dicarboxylate porphyrins may arise by the action of gut flora on heme[6] (whether the heme is of dietary origin or the result of gastrointestinal bleeding) and directly from the diet. There has been a report of excess consumption of brewer's yeast resulting in a fecal porphyrin profile indistinguishable from VP.[91] Therefore if the fecal porphyrin pattern resembles VP, plasma should be examined by fluorescence emission spectroscopy for the characteristic fluorescence maximum at 624 to 628 nm (Table 32-5).[117] If the fecal porphyrins (supplemented by plasma fluorescence emission spectroscopy) do not confirm VP or HCP (i.e., the raised fecal porphyrins are of dietary origin) then again the patient must have AIP. Assay of leukocyte coproporphyrinogen oxidase or protoporphyrinogen oxidase (the enzymes deficient in HCP and VP, respectively) is technically difficult, unnecessary, and may mislead. Analysis of urinary porphyrins is unhelpful in differentiating between the acute porphyrias.

Investigation During Clinical Remission

Sometimes the laboratory is asked to make a retrospective diagnosis of porphyria after the patient has fully recovered from an attack or as the cause of a chronic neuropsychiatric disorder some time after the onset of the illness. The first step is to quantify urinary PBG: screening tests are too insensitive for this purpose. Fecal porphyrin is measured (to exclude HCP) and plasma fluorescence emission spectroscopy performed (to exclude VP). If all of these tests are negative, it is very unlikely that symptoms are and/or were due to porphyria. However, it is difficult to exclude porphyria after long periods (i.e., several years) of clinical remission. Depending upon the degree of clinical suggestion, enzyme and DNA studies may be pursued but are often unrewarding.

Patients With Cutaneous Symptoms

The skin lesions of the cutaneous porphyrias are always accompanied by overproduction of porphyrins. The route of investigation should be dictated by the clinical presentation (Table 32-4).

Patients Complaining of Acute Photosensitivity

For suspected EPP, the essential investigation is measurement of whole blood (or erythrocyte) porphyrin using a sensitive fluorometric method. Screening tests using solvent extraction of blood or fluorescence microscopy of erythrocytes[123] are unreliable and should not be used.[27] If the erythrocyte and/or whole blood porphyrin concentration is within normal limits, EPP is excluded. If the concentration is increased, it is important to determine whether the increase is caused by free protoporphyrin, as in EPP, or ZPP, as in iron deficiency and lead toxicity. This requires extraction with a neutral solvent, such as ethanol[55] or acetone,[68] to prevent the demetalation caused by strong acids, followed by fluorescence spectroscopy or HPLC to distinguish free protoporphyrin from ZPP (fluorescence emission maxima 630 nm and 587 nm, respectively). Measurement of fecal protoporphyrin has no place in the diagnosis of EPP. Even if raised, erythrocyte porphyrin analysis is essential to exclude an increase caused by the action of gut flora on heme from the diet or from gastrointestinal bleeding.

Patients With Bullae/Fragility/Scarring

There are four main porphyrias in which clinically indistinguishable skin lesions occur (Table 32-4). The porphyrins that accumulate vary in solubility, and therefore testing both urine and feces is useful. Total urinary and fecal porphyrin should be measured by a spectrophotometric[8,27] or fluorometric[8] method, with adequate sensitivity and plasma porphyrins determined by fluorescence emission spectroscopy.[25,58] In practice, fecal analysis is often unnecessary because the two most common bullous porphyrias, PCT and VP, can be identified by analysis of urine and plasma (Table 32-5). If these tests are normal, then porphyria is excluded as the cause of any active skin lesions. Any increase in total urinary or fecal porphyrin should be further investigated by determination of individual porphyrins using a technique capable of resolving all porphyrins of clinical interest—including isomers.[90] Older separation methods based on solvent fractionation are unreliable.[30] The pattern observed in each of these porphyrias is unique (Table 32-5).

In PCT, excretion and plasma porphyrin concentrations return to normal during remission, with the proportions of individual porphyrins in urine and feces remaining abnormal for longer than total porphyrin concentrations. Thus in a patient whose skin lesions have healed, and whose total urinary and fecal porphyrin concentrations are normal, determination of individual porphyrins may reveal the diagnosis. The plasma fluorescence scan in VP and fecal coproporphyrin-III excretion in HCP remain abnormal for many years after clinical remission.

Relatives of Patients With Porphyria

Depending on the type of porphyria, screening relatives may be indicated.

Presymptomatic Diagnosis of Autosomal Dominant Acute Porphyrias

Screening family members to identify asymptomatic individuals who have inherited AIP, VP, or HCP, and are therefore at risk for acute attacks, is an essential part of management of families with these disorders. Screening may be carried out by metabolite measurement, enzyme assay, DNA analysis, or a combination of these approaches. The most sensitive metabolite assays for the presymptomatic diagnosis of each disorder are listed in Table 32-7.[7,71,77,93] These tests are almost always normal before puberty and therefore are not suitable for the investigation of children. In addition, urinary PBG excretion in AIP and the plasma fluorescence scan in VP may often be normal in asymptomatic adults shown by DNA analysis to be affected (Table 32-7). Measurement of the activity of the defective enzyme is more sensitive, but both sensitivity and specificity are limited by the overlap between activities in disease and in the normal population.[42,77,89] Erythrocyte HMBS assay is widely used for the presymptomatic diagnosis of AIP.[77]

Mutation detection by DNA analysis is specific and much more sensitive than biochemical methods.[42,52,77,89,120] It is therefore fast replacing other methods, particularly since it has the additional advantage of enabling asymptomatic disease to be excluded with certainty. However, it depends on prior identification of a disease-specific mutation in the family under investigation. In the 5% or so of families in which a mutation cannot be identified, gene tracking using intragenic single nucleotide polymorphisms (SNPs) may be helpful but requires at least two unequivocally affected family members.[35]

Other Porphyrias

Family investigation has a more limited role in the clinical management of other porphyrias. In PCT, the autosomal dominant familial form can be identified by erythrocyte UROD assay[108] or mutational analysis,[21,41] but there is as yet no evidence that family studies are necessary unless requested by anxious relatives.[40] However, patients of Northern European origin should be tested for the C282Y mutation in the hemochromatosis (*HFE*) gene and the families of homozygotes investigated for hemochromatosis. In EPP, testing the unaffected parent for the presence of the IVS3-48C low expression *FECH* allele is helpful for assessing the risk that a future child will have clinically overt disease.[63] Asymptomatic individuals from EPP families may wish to know whether they have inherited a severe *FECH* mutation, and thus have the potential to transmit the disease. FECH assay and/or mutation identification is required for this purpose[63,103]; erythrocyte protoporphyrin concentrations are rarely unequivocally abnormal in such individuals.

In the autosomal recessive porphyrias, CEP and ADP, screening families for asymptomatic carriers is not normally helpful, because the low carrier frequency in the general population makes the risk of transmission to the next generation very low. For severe homozygous or compound heterozygous porphyrias, such as CEP, ADP, HEP, and homozygous AIP, prenatal diagnosis may be indicated and has been reported for CEP[56] and HEP.[57]

ANALYTICAL METHODS

The analytical methods used in conjunction with porphyrias are described here briefly. Full descriptions are available on this book's accompanying Evolve site, found at http://evolve.elsevier.com/Tietz/textbook/.

Methods for Metabolites

The metabolite methods include those for ALA, PBG, and urinary, fecal, plasma, and blood porphyrins.

TABLE 32-7 Presymptomatic Diagnosis of Autosomal Dominant Acute Porphyrias: Metabolite Measurements in Asymptomatic Individuals With Porphyria Proven by Mutational Analysis

Porphyria	Metabolite	No. Individuals	Sensitivity	Specificity
AIP	Urine PBG*	84†	43%	100%
HCP	Fecal copro isomer I/III ratio†	11‡	64%	100%
VP	Plasma porphyrin fluorescence	109†	62%	100%

*Greater than 10.2 μmol/L.
†Aged 15 years or more.
‡Aged 7 years or more.

Specimen Collection and Stability

All samples must be protected from light; urinary porphyrin concentrations can decrease by up to 50% if kept in the light for 24 hours. Urinary porphyrins and PBG are best analyzed in fresh, random (10 to 20 mL) samples collected without preservative. Very dilute urine (creatinine less than 4 mmol/L) is unsuitable for analysis.

Although, with the exception of CEP, urine is often of normal color in the nonacute porphyrias, during the acute attack urine may be a reddish color because of the nonenzymatic condensation of PBG to uroporphyrins and other pigments.

Twenty-four-hour collections offer little advantage, delay diagnosis, and increase the risk of losses during the collection period. PBG and porphyrins are stable in urine in the dark at 4 °C for up to 48 hours and for at least a month at −20 °C. Specimens for ALA estimation should be promptly refrigerated. Urine specimens can be stored at 4 °C in the dark for at least 2 weeks without significant loss of ALA,[125] and frozen specimens are stable for weeks.[12] Whereas PBG is more stable around pH 8 to 9, ALA is more stable around pH 3 to 4, although more acidic environments notably reduce ALA stability.

About 5 to 10 g wet weight of feces is adequate for porphyrin measurements. Diagnostically, important changes in concentration are unlikely to occur with 36 hours at room temperature and samples are stable for many months at −20 °C.

Blood, anticoagulated with ethylenediaminetetraacetic acid (EDTA), shows no loss of protoporphyrin for up to 8 days at room temperature and for at least 8 weeks at 4 °C in the dark.

Available Methods for Porphyrin Precursors

PBG and ALA are water soluble and concentrate in the urine, and are therefore measured almost exclusively in the urine in the clinical laboratory. PBG is in general the more important of the precursors, whereas ALA is used more as a supplemental test.

Porphobilinogen

Most methods for PBG are based on the reaction of Ehrlich's reagent (dimethylaminobenzaldehyde in acidic solution) with the α-methene carbon of the pyrrole ring to form a colored product variously described as "rose red" or "magenta," which has a characteristic absorption spectrum with a peak at 553 nm and a shoulder at 540 nm. Porphyrins do not contain any α-methene hydrogens and so do not react. Some other substances in urine either react with the reagent to give red products, notably urobilinogen, inhibit the reaction, or are pigmented themselves and so mask the red chromogen.[25,160] All need to be removed. This is best achieved by ion-exchange chromatography (first described by Mauzerall and Granick[98]) but methods for accurate quantification of PBG based on this procedure are time consuming. More sensitive methods based on HPLC[76] and tandem-mass spectrophotometry (MS)[49] are available.

Qualitative screening tests in which urine is reacted directly with Ehrlich's reagent and assessed visually for the formation of the red chromogen (e.g., the Watson-Schwartz[150] and Hoesch[87] tests) are convenient but have been criticized for poor detection limits and interferences, even when solvent extraction has been used to separate the PBG-Ehrlich compound from the urobilinogen-Ehrlich complex.[16,17,27,135]

The Mauzerall-Granick method has been modified in attempts to produce an alternative that is acceptable for screening purposes. Buttery et al[18,19] avoided the use of columns by employing batchwise treatment with resin, and visually compared the final color with that of a surrogate calibrator. Blake et al[8] eliminated the centrifugation steps by using resin-filled syringes with detachable filters and compared the final color with a range of artificial calibrators. These modifications reduced the time taken to perform the test to 10 minutes and produced a semiquantitative result. A commercial kit based on Blake's method is available (Trace PBG Kit; Alpha Laboratories, Eastleigh, Hampshire, UK) and appears to be more analytically sensitive and specific for initial screening than qualitative, solvent extraction procedures.[32] A 2002 innovation uses resin-filled nylon sacs.[61]

If a qualitative screening test is used, it is essential to include appropriate controls and confirm all positive test results using a specific quantitative method.[29]

5-Aminolevulinic Acid

ALA can be measured directly[62] but is converted more usually into an Ehrlich's-reacting pyrrole by condensation with a reagent such as acetylacetone after separation from PBG by two-stage anion exchange chromatography. A method for the measurement of PBG and ALA, based on that of Mauzerall and Granick, is available commercially (Bio-Rad Laboratories, Hercules, Calif.). An alternative photometric method has been proposed[20] for more rapid testing.

Compared with PBG procedures, interferences are much more common with ALA. For example, the acetylacetone derivatization step can form a compound with penicillin that reacts with Ehrlich's reagent.[81]

Method for the Determination of Porphobilinogen in Urine

The PBG procedure described on the Evolve site that accompanies this book uses commercially available ion-exchange columns, but some laboratories might prefer to prepare an ion-exchange resin themselves.[18,19,135] PBG in the resin eluate reacts with Ehrlich's reagent to form a colored product that is scanned in a spectrometer.

Reference intervals are given in Table 32-3. Scanning the spectrum of the product is essential if interferences are to be identified. Imipenem, for example, often gives a peak at 580 nm with Ehrlich's reagent.[148] The coefficient of variation at the cutoff of 9 μmol/L is approximately ± 10%, but becomes considerably less precise at lower concentrations. For this reason, very dilute urines (creatinine <1.5 μmol/L) are unsuitable.

Urinary PBG that is raised at least 2 to 3 times the upper reference limit is diagnostic of an acute porphyria. However, porphyria is not necessarily the cause of symptoms (see discussion in the section on investigation of acute porphyria). Further investigation is necessary to identify the type of porphyria. Normal PBG excretion in the presence of symptoms provides very strong evidence against those symptoms being caused by acute porphyria.

Analysis of Porphyrins in Urine and Feces

Methods for porphyrin fractionation are complex and time consuming and not available in every laboratory. For this reason, simple qualitative screening tests are often used to exclude the majority of specimens that do not require further investigation from the few that justify fractionation of the individual porphyrins. Screening tests in which extracts of urine or feces are examined visually for typical red-pink fluorescence of porphyrins lack sensitivity and should not be used.[27] Methods based on spectrophotometric scanning of acidified urine or fecal extracts for the presence of the Soret band are recommended and yield semiquantitative information.[29] Quantitative fluorometric methods are also available.[8]

All methods for the fractionation of porphyrins are based on the different solubilities of individual porphyrins caused by their different β-substituents and to a lesser extent on the substituent order around the macrocycle. Thus methods include differential extraction with solvents, paper and thin layer chromatography, and HPLC.[45,129] Solvent extraction methods should not be used, because they yield only limited and sometimes misleading information.[30] Reversed-phase HPLC is the current method of choice and separates all porphyrins of clinical interest, including isomers and metal chelates, without the need for prior methylation.[5,75,124] Spectrophotometric or fluorometric detection can be used; the latter has superior sensitivity and specificity is preferred.

Semiquantitative Method for Total Porphyrin in Urine

This simple method for total urine porphyrins uses scanning spectrometry and is described fully on the Evolve site that accompanies this book A typical spectrum is shown in Figure 32-3.

Reference values are given in Table 32-3. The method is reproducible but only semiquantitative. The detection limit depends on the amount of background absorbance but concentrations of approximately 50 nmol/L should be detected in urine of normal color. Ideally, concentrations should be expressed as a ratio to creatinine concentration to correct for urine concentration.

Very occasionally, urine contains substances that produce a very high background absorbance, making identification of any peak in the 400-nm region difficult. Such samples require analysis by alternative methods, such as HPLC.

Increased concentrations require further investigation to identify individual porphyrins; porphyria should not be diagnosed on the basis of increased total porphyrin alone.

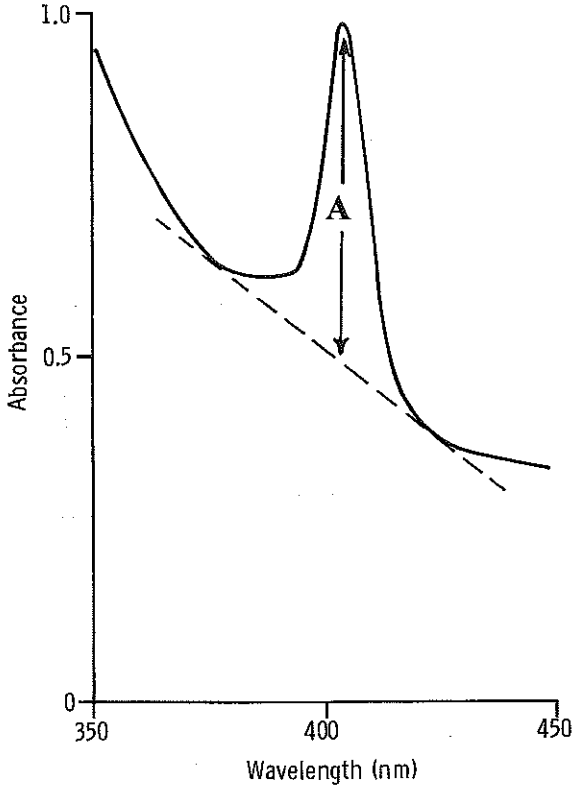

Figure 32-3 Absorption spectrum of acidified urine showing the procedure for the measurement of corrected absorbance *(A)* of the porphyrin peak.

Semiquantitative Method for Total Porphyrin in Feces

This simple method for total fecal porphyrins uses scanning spectrometry after extraction[26,92] and is described fully on the Evolve site that accompanies this book.

Reference values are given in Table 32-3. The expression of concentration on a dry weight basis corrects for the moisture content of feces. Total fecal porphyrin determined by this method, unlike most tests based on solvent extraction, includes uroporphyrin.[127]

Very occasionally, feces contain substances that produce a very high background absorbance, making identification of any peak in the 400-nm region difficult. Such samples require analysis by alternative methods, such as HPLC.

Increased total fecal porphyrin concentration requires further investigation by fractionation, identification, and quantification of individual porphyrins using a technique, such as HPLC, that resolves coproporphyrin I and III isomers. Porphyria should never be diagnosed on the basis of raised total fecal porphyrin alone.

HPLC Fractionation of Porphyrins in Urine and Feces

This complex method for urine and fecal porphyrins uses sample preparation, HPLC separation, and fluorometric detection.[122] It is described in detail on the Evolve site that accompanies this book. The samples are assayed with and

without addition of calibrator to assist with fluorometric peak identification.

Figure 32-4 shows typical profiles from patients with various types of porphyria.

In addition to the biosynthetic porphyrins, several isocoproporphyrins may be found in feces of patients with PCT,[39] some of which may not be completely resolved.

For diagnostic purposes, quantification of individual porphyrins is rarely necessary, particularly if the concentrations are clearly elevated. Table 32-5 shows expected findings in the various types of porphyria, and reference values for individual porphyrin fractions are given in Table 32-3. There is considerable variation in the reference values quoted in the literature,[145] probably a consequence of the difficulties in calibration.

The extraction method for fecal porphyrins results in some interference with the chromatography caused by a proportion of the diethyl ether dissolving in the aqueous phase. As a result an extra peak elutes just before the uroporphyrin position. This peak contains any uroporphyrin in the sample, up to 50% of the heptacarboxylate porphyrins and smaller amounts of hexacarboxylate and pentacarboxylate porphyrins.

Methods for Blood Porphyrins

The methods described below require a spectrofluorometer fitted with a red-sensitive photomultiplier. If such equipment is not available locally, samples should be referred to a specialized laboratory because erythrocyte and plasma measurements are required rarely for the urgent assessment of acutely ill patients.

Determination of Erythrocyte Total Porphyrin

This method for erythrocyte total porphyrin uses double extraction and fluorometry.[8,114,115] It is described in detail on the Evolve site that accompanies this book.

Reference intervals are given in Table 32-3. Total erythrocyte porphyrin concentrations are increased in EPP, CEP, the rare homozygous variants of the autosomal dominant porphyrias, iron deficiency, hemolytic anemia, some other forms of anemia, and lead poisoning. A normal total porphyrin concentration excludes the diagnosis of EPP. Distinction between EPP and other causes of increased erythrocyte total porphyrin concentration requires differentiation between protoporphyrin and its zinc chelate because the acidic condition of this assay dissociates the zinc chelate and provides only a measure of total porphyrin.

Qualitative Determination of Zinc-Protoporphyrin and Protoporphyrin

This qualitative method for ZPP and protoporphyrin uses extraction and fluorometry.[55] It is described in detail on the Evolve site that accompanies this book.

Emission peaks for ZPP and free protoporphyrin are 587 nm and 630 nm, respectively. If the main peak is at 587 nm, EPP is excluded, whereas a pronounced predominance of the peak at 630 nm confirms the diagnosis of EPP (see Figure 32-5). With experience, this test can be used to screen for EPP without the necessity for quantitative analysis. It is possible to quantify both ZPP and protoporphyrin by measuring the peak heights at 587 nm and 630 nm above a constructed baseline if calibrator solutions of both protoporphyrins are prepared, providing allowance is made for a contribution of fluorescence from ZPP at the maximum for free protoporphyrin.[28] A limitation of this method is that the efficiency of the extraction of ZPP is only about 50%.[28]

Analysis of Plasma Porphyrins

Plasma porphyrins may be determined by fluorescence emission spectroscopy of saline-diluted plasma[25,58,117] or deproteinized extracts,[93] or by HPLC.[73] The first of these methods has the advantages of simplicity and including porphyrins that are bound covalently to plasma proteins and is detailed below.

Fluorescence Emission Spectroscopy of Plasma Porphyrins

This method detects the fluorescent emission of plasma porphyrins when excited at 405 nm.[58,117] It is described in detail on the Evolve site that accompanies this book.

Figure 32-6 shows typical fluorescence emission maximum wavelengths for the cutaneous porphyrias. The plasma in VP contains porphyrin covalently bound to protein with a fluorescence emission maximum at 624 to 628 nm.[117] In other porphyrias, porphyrin is noncovalently bound to albumin and hemopexin.[83] A normal fluorescence emission scan in plasma from a patient with clinically active skin lesions excludes all cutaneous porphyrias as their cause.[31,58] The scan may become normal in PCT and HCP as skin lesions heal, and the diagnosis may be missed unless individual porphyrins are also measured in urine and feces from such patients. In addition, the scan may be abnormal during an acute attack of AIP or HCP in the absence of skin lesions and is always abnormal in clinically manifest VP, whether skin lesions are present or not (Table 32-5).

The plasma porphyrin concentration may be increased in conditions in which porphyrin excretion is impaired, such as renal failure and cholestasis. Although plasma porphyrin concentrations are usually higher in chronic renal failure with PCT than in renal failure alone,[116] unequivocal diagnosis of PCT in this situation is best achieved by fecal porphyrin analysis[60] or fractionation of plasma porphyrins by HPLC.[73]

Enzyme Measurements

Assay of the individual enzymes of the heme biosynthetic pathway is rarely required for the investigation of patients with symptoms of porphyria. However, measurement of enzyme activities is useful for family studies when the individual mutation cannot be identified or when DNA analysis is not available, and for the identification of subtypes such

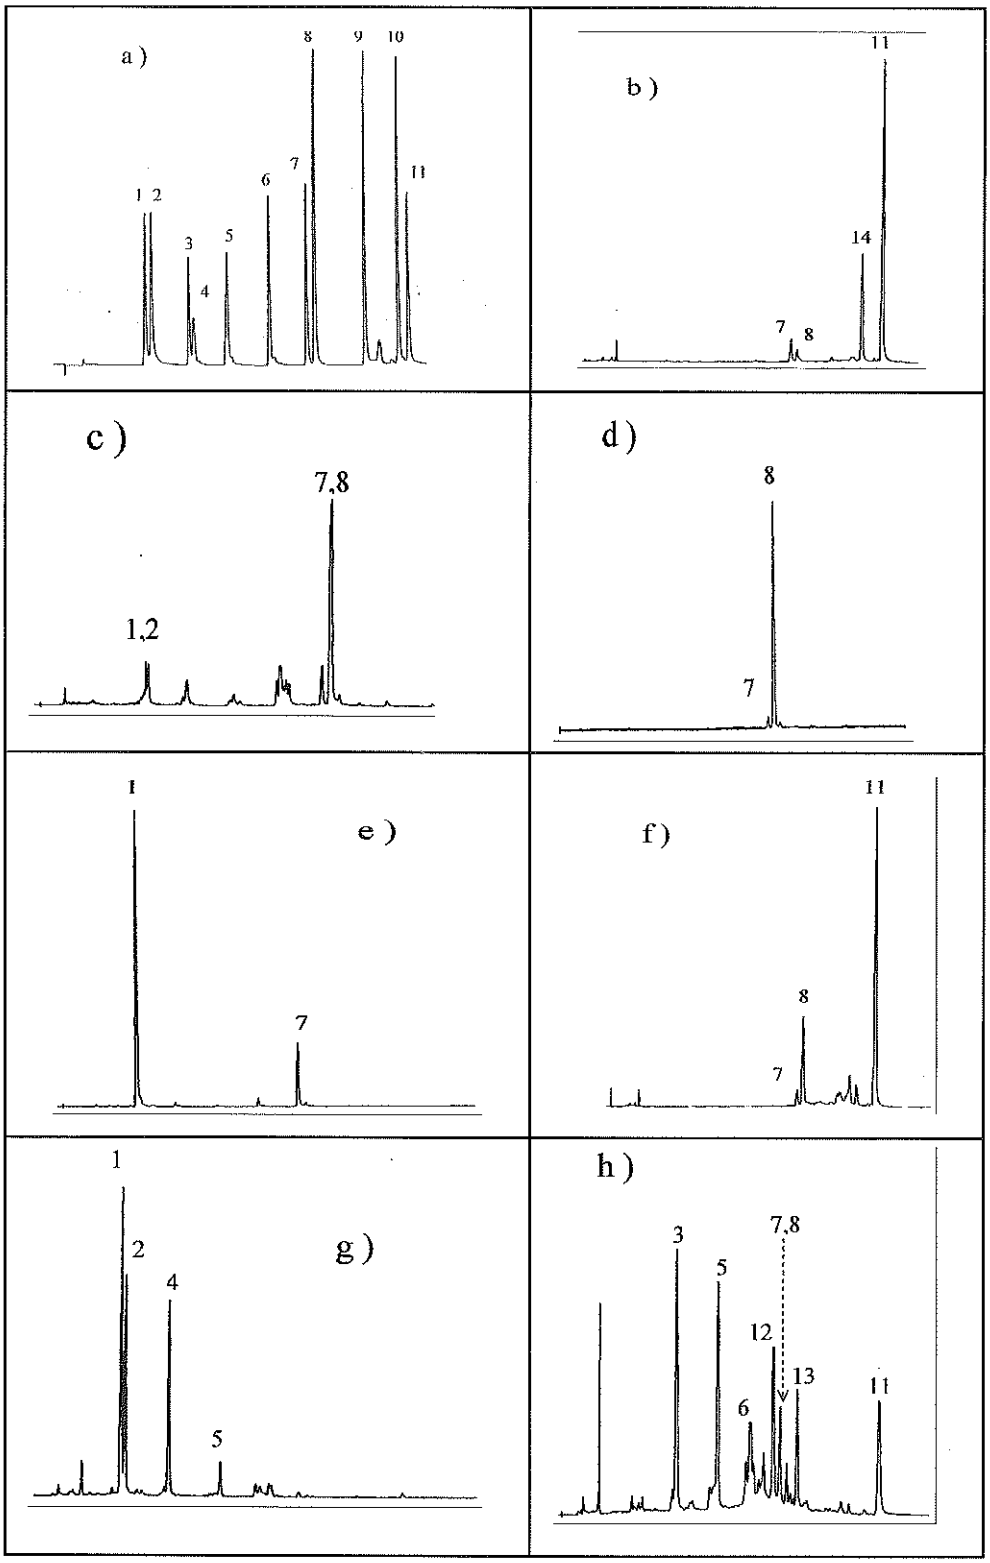

Figure 32-4 Representative HPLC chromatograms for *(a)* working standard; *b,* normal feces; *c,* normal urine; *d,* feces—hereditary coproporphyria; *e,* urine—congenital erythropoietic porphyria; *f,* feces—variegata porphyria; *g,* urine—porphyria cutanea tarda; and *h,* feces—porphyria cutanea tarda chromatographic conditions as described in the appendix on the Evolve site that accompanies this book. Figure 32-6 Fluorescence emission spectra (excitation 405 nm) of dilutions in phosphate buffered saline (PBS) of plasma from a normal individual and patients with various porphyrias.

as nonerythroid AIP and "homozygous" forms of autosomal dominant porphyrias. Erythrocytes are a convenient source of cytoplasmic enzymes (ALAD, HMBS, UROS, and UROD)[33,46,56,133] but assay of the mitochondrial enzymes (CPO, PPOX, and FECH)[34,66,128] requires nucleated cells, such as leukocytes or cultured fibroblasts.[25] Assays for enzymes that use porphyrin*ogens* as substrates are particularly difficult because the substrate is unstable, has to be prepared in situ and, particularly with protoporphyrinogen, undergoes nonenzymatic oxidation during the assay. However, erythrocyte HMBS measurement is relatively straightforward and will be described in detail.

Assay of Erythrocyte Hydroxymethylbilane Synthase Activity

This enzymatic assay determines the amount of porphyrinogens formed from an excess of added PBG over the course of 30 minutes. It is described in detail on the Evolve site that accompanies this book.

The reference interval for this method[157] (mean ± 2 standard deviation [SD]) is 20 to 42 nmol uroporphyrin per milliliter of erythrocytes per minute at 37 °C.

HMBS activity is usually below the reference interval in AIP, except in the uncommon nonerythroid form; but there is overlap between activities in AIP and normal individuals.[120] After exclusion of families with nonerythroid AIP, HMBS activity has been reported to have a sensitivity of 84% and a specificity of 77% for detection of AIP in patients without symptoms.[52] In France the prevalence of abnormally low HMBS activities in the general population is about 1 in 800.[111]

For family studies, where the incidence of AIP is quite high, the predictive values of positive and negative test results are reasonable, and HMBS assay is helpful, although not foolproof, in assigning AIP status. In the general population, where the incidence of disease-specific mutations in the *HMBS* gene is in the order of 1 in 15,000, the predictive values are too low for the test to be of any value.

HMBS activity falls markedly as red cells age, so that any shift in their age distribution will be reflected in measured

activity. Increased erythropoiesis may raise activity sufficiently to mask an inherited deficiency. Measurement of erythrocyte HMBS activity is therefore not reliable for the presymptomatic detection of AIP in subjects who are hematologically abnormal, have received a recent blood transfusion, or are less than 1 year old. Activity may also be increased in liver disease and in chronic alcohol abuse.

DNA Analysis

Screening families for porphyria by DNA analysis is a two-stage process. First, the mutation that causes porphyria in the family under investigation needs to be identified by analysis of DNA from a family member in whom the diagnosis of a specific type of porphyria has been established unequivocally. Second, that patient's relatives are then screened for the mutation. The first part of this process is the more complex. Because most mutations are restricted to one or a few families, identification of a mutation in a new family almost always requires analysis of the entire gene or at least all exons with their flanking intronic sequences and the promoter region. Initial testing for a single mutation is worthwhile only in those countries where founder mutations predominate, for example, VP in South Africa and AIP in Sweden.

Mutation Detection

Two main approaches are used to analyze a gene for the presence of a mutation (see also Chapter 37). The gene may either be screened to find the region that contains the mutation, and then only that region sequenced to identify the mutation, or all regions of the gene likely to contain the mutation may be sequenced directly. Prior screening considerably decreases the amount of sequencing that is required, but this is becoming a less important consideration as DNA sequencing becomes cheaper and more straightforward with development of ever better automated fluorescence sequencers.

Denaturing gradient gel electrophoresis (DGGE), single-strand conformational polymorphism (SSCP) analysis, heteroduplex analysis, and denaturing HPLC have all been used to screen the *HMBS* and other porphyria genes for mutations.* DGGE is currently the most widely used technique and is very sensitive† but requires gradient gels and polymerase chain reaction (PCR) primers with guanine cytosine (GC) extensions. Denaturing HPLC, though still requiring amplification of the gene in small fragments (about 500 bp), is rapid, simple, and robust. It has been shown to have high sensitivity for detection of mutations in many genes[159] and has the potential to replace DGGE as the method of choice.

Once the mutation that causes porphyria in a family has been identified, relatives are then screened for its presence either by using one of the screening methods listed above, by direct sequencing of the region containing the mutation, or by some other mutation-specific method (see Chapter 37).

A method for identifying mutations in the human *HMBS* gene by direct sequencing is described later in this chapter. The method can be adapted for other porphyria genes by using the appropriate amplification and sequencing primers. Primer sequences have been published for the *PPOX*,[151] *CPO*[102], *UROD*[103], *FECH*[107], and *UROS*[33] genes.

Mutation Analysis of the Human *HMBS* Gene by Direct Sequencing

PCR is used to amplify some of the exons of the *HMBS* gene, which are then sequenced using the Sanger method. If no mutations are found, the remaining exons and the 5′ intron are evaluated. If a mutation is found in an exon, it is re-sequenced in the reverse direction.

In a prospective study of 198 unrelated patients with proven AIP, this method detected a mutation in 97% of patients. Almost all mutations were detected by sequencing in one direction only; only rarely was sequencing in the opposite direction required to reveal an abnormality. Because amplified genomic DNA is sequenced directly, without subcloning, the risk of PCR artifacts is very low and is essentially eliminated by sequencing a new PCR product in the opposite direction to confirm each mutation. Complete gene deletions and large partial deletions that prevent the binding of primers are not detected by this method, because only the normal allele will be amplified for sequencing. Such deletions or mutations that lie outside the regions that are sequenced may explain the failure to find an abnormality in all patients.

In most countries, about one third of the mutations that are identified will not have been reported previously in AIP and may represent rare polymorphisms rather than disease-specific mutations. Criteria that suggest that such novel mutations cause disease include production of a frameshift or stop codon, the absence of any other sequence abnormality in the gene, segregation with disease, and nonconservative change of an amino acid residue that is conserved between species and/or known to have a functional role in catalysis. Mutations of consensus bases in splice sites are also likely to be disease specific, but ideally all putative splicing defects should be confirmed by analysis of mRNA. Proof that a missense mutation causes disease may require expression and characterization of the mutant enzyme in a prokaryotic or eukaryotic vector.

Identification of a Functional Polymorphism in *FECH* Gene

The method is described in detail on the Evolve site that accompanies this book. It tests for the presence of the IVS3-48C FECH allele. This allele causes decreased expression of FECH because substitution of the T nucleotide at IVS3-48 by a C nucleotide leads to enhanced use of an alternative splice site with increased formation of an unstable mRNA for FECH.[63]

*References 21, 86, 102, 103, 110, 111, 120, 130, 136, 143, 151, 152.

†References 21, 110, 120, 130, 143, 151.

The IVS3-48C allele is carried by about 12% of the Western European population. If it is not present in the partner of a patient with overt EPP, and they have not previously had a child with overt EPP, the risk that the couple will have a child with overt EPP is less than 1 in 50, whereas if it is present, the risk is about 1 in 4. Investigation for the presence of the IVS3-48C allele in the parents of a child with overt EPP is usually not helpful because in such families the risk of overt EPP in subsequent children is 1 in 4, irrespective of whether the unaffected partner carries the low expression allele. Testing a newborn child for the low expression allele may also be useful for predicting the child's risk of later developing symptoms.

CHAPTER 33

Therapeutic Drugs and Their Management

Thomas P. Moyer, Ph.D., and Leslie M. Shaw, Ph.D.

Therapeutic drug management (TDM) is a multidisciplined clinical activity initiated by the physician ordering laboratory quantification of drug concentration in a biological fluid to assess therapeutic compliance, efficacy, or to elucidate—the cause of drug-induced toxicity. The medical professionals involved in TDM include the ordering physician, clinical laboratorian, clinical pharmacologist, and nurses involved in medication delivery.

The limitations of empirical drug dosing such as standard or fixed dose regimens have long been recognized by physicians, who have responded with all of their clinical skills and knowledge of basic pharmacology to individualize each patient's drug dosage. TDM offers the physician a scientific rather than empiric approach to selecting a drug regimen to optimize therapy. The practice of TDM facilitates improved response to therapy by providing the prescribing physician with objective information about drug disposition; TDM describes a patient's pharmacokinetic status at the moment of specimen collection.

Pharmacokinetics is the science that describes the relationship between drug dose and the time course of drug absorption, distribution, and elimination that results in a specific drug concentration in biological systems.[93,119,150] Clinical pharmacokinetics involves the application of mathematical relationships to predict whether a drug concentration quantified at a specific time reflects normal or abnormal distribution and metabolism in a unique patient. Abnormal evaluation derived by this exercise may be the result of significant factors such as genetics, drug-drug interaction, organ failure, or patient noncompliance. Clinical pharmacokinetics can also be applied to predict appropriate change in dose or dosing interval to allow for safe and effective treatment and to attain optimal response to the drug as quickly as possible. It is important therefore for the clinician and laboratorian to understand not only how to quantify drugs in biological specimens but how these results are used to achieve effective drug therapy. As mentioned earlier, TDM is a multidisciplinary approach that relies on the cooperative efforts of the physician, nurse, pharmacologist, pharmacist, and clinical laboratorian.

To be effective, TDM requires the acquisition of a valid specimen followed by timely determination of the drug concentration in the specimen and interpretation of results in the context of dose, time of last dose, and other drugs present. Results should be reported or collated with the dosing schedule so that they may be interpreted in a pharmacokinetic context.

Knowledge of the impact of genetics on drug disposition developed rapidly in the late 1990s and continues to develop in the early 2000s. This knowledge field as it relates to drug disposition has become known as pharmacogenomics. TDM and pharmacogenomics are highly interactive disciplines used in conjunction to elucidate the overall pharmacokinetic status of an individual patient. While the basic concepts of pharmacogenomics are outlined elsewhere in this text (Chapter 43), the specific aspects of the discipline that relate to the interpretation of TDM results are included in this chapter. Reviews by O'Kane[101] and Weinshilboum,[147] and the Internet website offered by Flockhart[37] are good sources for additional information.

This chapter focuses on the laboratory's role in the discipline of TDM. Excellent descriptions of the roles of the physician and consulting pharmacologist are presented in Melmon and Morrelli's *Basic Principles in Therapeutics,*[81] Goodman and Gilman's *The Pharmacological Basis of Therapeutics,*[51] and Mandell and colleagues' *Principles and Practice of Infectious Diseases.*[78] The *Physicians' Desk Reference* (PDR), published annually by Medical Economics

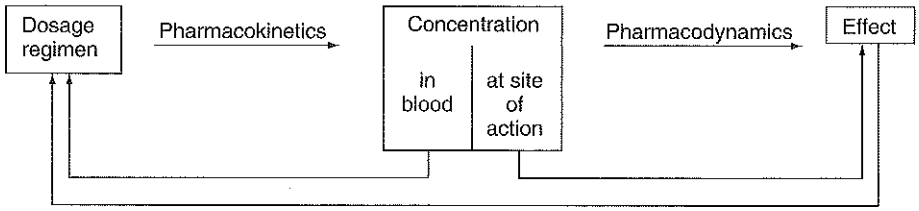

Figure 33-1 Conceptual relationship between pharmacodynamics and pharmacokinetics.

of Montvale, New Jersey, is also an excellent source of dosing guidance and pharmacokinetic information.

DEFINITIONS

Pharmacology comprises that body of knowledge surrounding chemical agents and their effects on living processes. This is a broad field, and it has traditionally been confined to those drugs that are useful in the prevention, diagnosis, and treatment of disease. *Pharmacotherapeutics* is that part of pharmacology concerned primarily with the application or administration of drugs to patients for the purpose of prevention and treatment of disease. For this aspect of medical practice to be effective, the pharmacodynamic and pharmacokinetic properties of drugs should be understood.

Pharmacodynamics encompasses the processes of interaction of pharmacologically active substances with target sites, and the biochemical and physiological consequences leading to therapeutic or adverse effects.[29] For many drugs, the ultimate effect or mechanism of action at the molecular level is understood poorly, if at all. However, effects at the cellular or organ system level or in the whole body are relatively well understood and can usually be related to dose of the drug.

Pharmacokinetics describes the processes of the uptake of drugs by the body, the biotransformations they undergo, the distribution of the drugs and their metabolites in tissue, and the elimination of the drugs and their metabolites from the body. Clinical pharmacokinetics is the discipline that applies the principles of pharmacokinetics to safe and effective therapeutic management of an individual patient. It is this aspect of pharmacology that most strongly influences the interpretation of TDM results and that is dealt with in more detail in this chapter.

Note that the term "pharmacology" relates to the broad knowledge of the systemic effects of a drug; "pharmacodynamics" refers to the interaction of a drug at its site of action; and "pharmacokinetics" is a mathematical description of drug disposition. These terms are quite different and should not be used interchangeably.

Figure 33-1 illustrates the conceptual relationship between pharmacodynamics and pharmacokinetics. The former relates drug concentration at the site of action to the observed magnitude of the effect. Pharmacokinetics, on the other hand, relates dose, dosing interval, and route of administration (regimen) to drug concentration in the blood. For more complete discussions of these basic concepts, the reader is encouraged to review standard textbooks of pharmacology.[51,81,87,88,119]

Toxicology is the subdiscipline of pharmacology concerned with adverse effects of chemicals on living systems. Toxic effects and mechanisms of action may be different from therapeutic effects and mechanisms for the same drug. Similarly, at the high dose of drugs at which toxic effects may be produced, rate processes are frequently altered compared with those at therapeutic doses. For these reasons, the terms *toxicodynamics* and *toxicokinetics* are now applied to these special situations.

BASIC CONCEPTS

The pharmacological effect of a drug is elicited by direct interaction of the drug with a receptor controlling a specific function or by a drug-mediated alteration of the physiological process regulating the function; this is known as the mechanism of action. In a given tissue, the site at which a drug acts to initiate events leading to a specific biological effect is called the *site of action* of the drug. For most drugs, the intensity and duration of the observed pharmacological effect are proportional to the concentration of the drug at the receptor, predicted by pharmacokinetics.

Mechanism of Action

The *mechanism of action* of a drug is the biochemical or physical process occurring at the site of action to produce the pharmacological effect. Drug action is usually mediated through a receptor. Cellular enzymes and structural or transport proteins are important examples of drug receptors. Nonprotein macromolecules may also bind drugs, resulting in altered cellular functions controlled by membrane permeability or DNA transcription. Some drugs are chemically similar to important natural endogenous substances and may compete for binding sites. In addition, some drugs may block formation, release, uptake, or transport of essential substances. Others may produce an effect by interacting with relatively small molecules to form complexes that actively bind to receptors. These and other examples of receptor binding are more completely discussed in pharmacology texts.*

*References 51, 81, 87, 88, 93, 119.

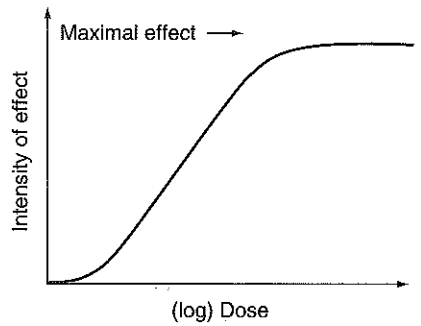

Figure 33-2 The log dose-effect relationship. The plateau (maximum effect) is likely due to saturation at the receptor.

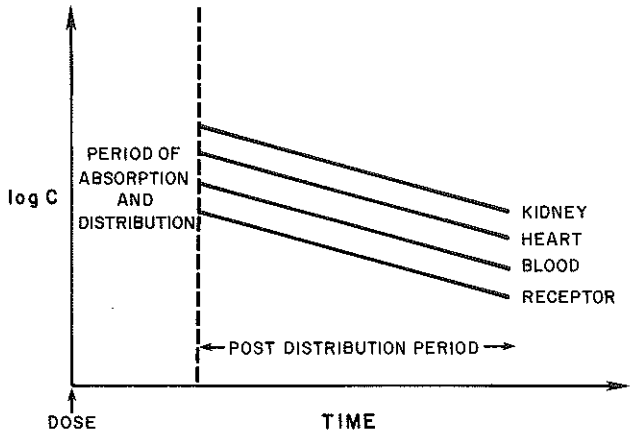

Figure 33-3 Property of kinetic homogeneity. Blood concentration of drug correlates with, but may not be equal to, the concentration in tissue and at the receptor site.

Although the exact molecular interactions that describe the mechanism of action remain obscure for many drugs, theoretical models have been developed to explain them. One concept postulates that a drug binds to intracellular macromolecular receptors through ionic and hydrogen bonds and van der Waals forces. This theoretical model further postulates that if the drug-receptor complex is sufficiently stable and able to modify the target system, an observable pharmacological response will occur. As Figure 33-2 illustrates, the response is dose dependent until a maximum effect is reached. The plateau may be due to saturation at the receptor or overload of a transport process.

The utility of monitoring drug concentration is based on the premise that pharmacological response correlates with the concentration of the drug at the site of action (receptor). Measurement of the concentration at the receptor site in a patient is technically impractical, if not impossible. However, studies have shown that for many drugs a strong correlation exists between the serum drug concentration and the observed pharmacological effect. In addition, years of relating blood concentrations to drug effects have demonstrated the clinical utility of drug concentration information. One must nevertheless always keep in mind that a serum drug concentration does not necessarily equal the concentration at the receptor; it merely reflects it. However, for pharmacokinetic studies it is assumed that changes in drug concentration in blood (or serum) versus time are proportional to changes in local concentrations at the receptor site or in body tissue. This assumption is sometimes called the *property of kinetic homogeneity* and is applicable to all pharmacokinetic models in postabsorptive and postdistributive phases of the time course. Figure 33-3 illustrates that property for a hypothetical compound. Parallel concentrations (log C) are expected in blood at the receptor and in tissue as time passes. Figure 33-3 is hypothetical; the absolute concentration of a drug in various tissues is highly variable from drug to drug.

The property of kinetic homogeneity is an important assumption in TDM because it is the basis on which all therapeutic and toxic concentration reference values are established. Measurable concentration ranges collectively define a

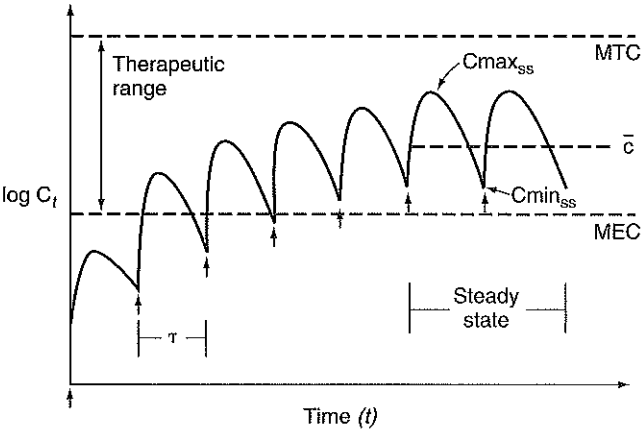

Figure 33-4 The peak, median, and trough drug concentrations increase with multiple identical doses administered once each half-life until they reach steady state. For most drugs, it takes five to seven half-lives to reach steady state. At steady state, optimal peak and trough concentrations are less than the MTC and greater than the MEC. The range of values between MEC and MTC is referred to as the "therapeutic range." C_{maxss} and C_{minss}, maximum and minimum steady-state concentrations; C, average steady-state concentration; τ, dosing interval; D, dose; *MTC*, minimum toxic concentration; *MEC*, minimum effective concentration. *(Modified from Gilman AG, Goodman L, Gilman A, Eds. The pharmacological basis of therapeutics, 6th ed. New York: Macmillan, 1980. Reproduced with permission of The McGraw-Hill Companies.)*

therapeutic range (Figure 33-4) that represents the relationship between *minimum effective concentration* (MEC) and *minimum toxic concentration* (MTC). In the optimal dosing cycle, the *trough blood concentration* (the lowest concentration achieved just before the next dose) should not fall below the MEC, and the *peak blood concentration* (the highest concentration achieved within the dosing cycle) should not rise higher than the MTC. This is usually achieved by adminis-

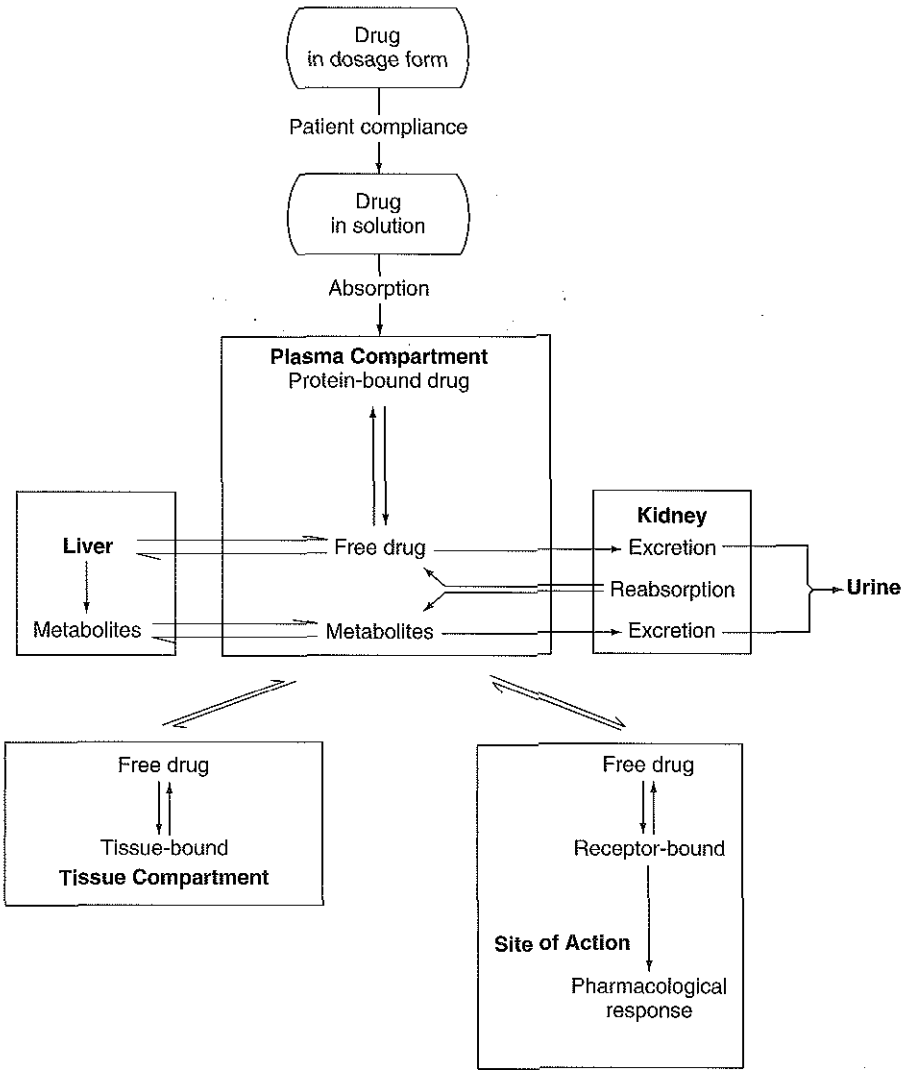

Figure 33-5 Factors affecting plasma drug concentration. *Absorption:* Drug must be formulated to ensure bioavailability for absorption from the gastrointestinal tract or other administration site. *Metabolism:* Drug is converted to a more soluble compound (metabolite), which may be pharmacologically active or inactive. Metabolism may occur in tissue other than the liver. *Excretion:* The more water-soluble drugs and their metabolites are usually excreted in urine. Excretion may also occur via bile, feces, saliva, and expired air. *Tissue storage:* The drug may be stored in tissue that exhibits no pharmacological response to it; side effects may occur from drug interaction with a specific physiological system. *Site of action:* Free drug binds to the receptor and produces pharmacological response. The number and type of receptors to which the drug is bound determine the intensity and duration of the observed response. *(Modified from Pippenger CE. TDM: Principles of drug utilization. Syva Monitor. San Jose: Syva Co. November, 1978:1,3-5.)*

tering the drug once every half-life, denoted by τ in Figure 33-4. Multiple dosing regimens should achieve *steady-state* serum drug concentrations consistently greater than the MEC and less than the MTC within the therapeutic range. Steady state is the point at which the body concentration of the drug is in equilibrium with the rate of dose administered and the rate of elimination. Blood concentrations greater than the MTC put patients at risk for toxicity; concentrations less than the MEC put them at risk for the disorder that the drug is supposed to treat. MTC and MEC are useful guidelines in therapy; this concept is incorporated into tables presented later in this chapter summarizing specific drug data. Doses must be planned to achieve therapeutic concentrations, and these must be monitored to guide adjustment of dose if necessary. The smaller the difference between MEC and MTC, the smaller the therapeutic index and the more likely TDM will be necessary. The key concept to remember is that the MEC and MTC define the therapeutic range for most drugs.

PHARMACOKINETICS

As defined previously, pharmacokinetics is the study of the rate processes of absorption, distribution, biotransformation, and excretion of drugs, poisons, and chemicals of both exogenous and endogenous origin. Figure 33-5 depicts in detail the many factors affecting drug concentration and pharmacological response.

In pharmacokinetics, mathematical approaches are used to predict or describe certain events, usually for calculating a dosing regimen or predicting the serum drug concentration after a given drug dose. The mathematical tools most often used in clinical pharmacokinetics are compartmental models and model-independent relationships.

Compartmental Models

Compartmental models have been the foundation of pharmacokinetic data analysis. The compartmental approach is presented here to facilitate definition of important pharmacokinetic parameters. Compartmental models are determin-

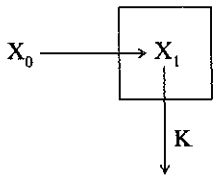

Figure 33-6 A one-compartment pharmacokinetic model.

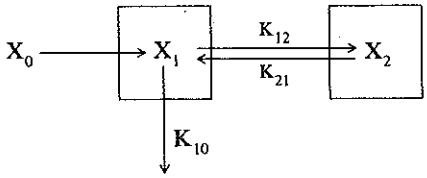

Figure 33-7 A two-compartment pharmacokinetic model.

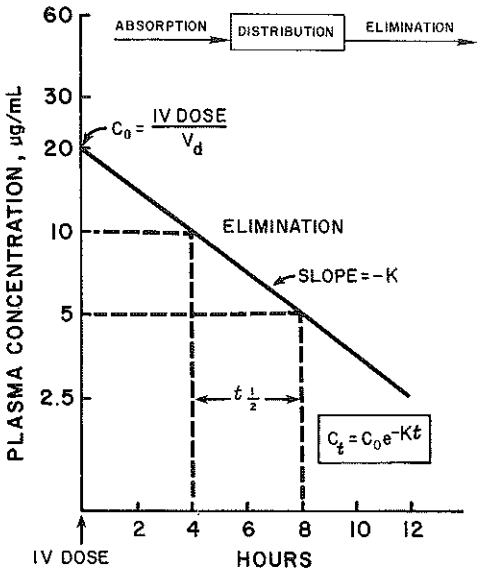

Figure 33-8 Drug concentration in plasma after intravenous administration of a single dose. The data show mono-exponential decline, which describes a one-compartment model.

istic in nature; drug concentration and time determine or define the model. The number and values of compartments assigned to the model have no true physiological meaning or anatomical reality. The intravascular fluid compartment (blood) usually is the anatomical reference compartment. The advantage of intravascular fluid as the reference compartment is the ease with which it may be sampled to provide a definitive profile of blood concentration of drug versus time. The actual number of compartments can be quite extensive. However, for the sake of simplicity, one-, two-, and three-compartment models are used most often.

In a one-compartment model, the body is considered as a single compartment (Figure 33-6). It is assumed that after introduction of a drug, the substance is rapidly and uniformly distributed throughout the body. Such a model is frequently applied to water-soluble antibiotics, such as gentamicin. In contrast, the two-compartment model (Figure 33-7) accounts for an initial decline of drug concentration in the reference compartment because of distribution from the plasma into vascularized tissue (the second compartment). The three-compartment model mimics a system like the two-compartment model with a third reservoir, such as adipose tissue or cellular nuclei, in which the drug resides over the long term. In Figures 33-6 and 33-7, X_0 represents the drug dose given and therefore the amount of drug in the system at zero time; X_1 the amount of drug in the central or reference compartment; and X_2 the amount of drug in the peripheral compartment in the case of the two-compartment model. The *k*s are first-order rate constants; k and k_{10} are elimination rate constants, because they describe the rates at which the drug leaves the reference compartment and is lost from the system. k_{12} and k_{21} are transfer rate constants describing, for the two-compartment model only, rates at which the drug is exchanged between compartments within the system. Figure 33-8 illustrates graphically the relationship between log of concentration and time for the one-compartment model. The curve in Figure 33-8 is described by the following equation:

$$C_t = C_0e^{-kt} \quad (1)$$

where C_0 is the initial plasma concentration of the drug; C_t is the blood concentration of the drug as a function of time; and k is the first-order elimination rate constant. C_0 is estimated by extrapolating the line shown in Figure 33-8 to zero time. From knowledge of C_0 and k, one can theoretically predict C at any time (C_t), or one can determine k, and C_0, and C_t either graphically or mathematically. As shown later, most drugs are administered in repetitive doses rather than in a single bolus.

Figure 33-9 illustrates the more complex kinetics demonstrated by the two-compartment model. The curve is described by the following equation:

$$C_t = Ae^{-\alpha t} + Be^{-\beta t} \quad (2)$$

where the rate constant alpha (α) is the slope of the curve during the phase in which the drug is being distributed, referred to as the *distribution phase.* Beta (β) is the slope of the curve during the phase in which the drug is being eliminated by metabolism and excretion (assuming that distribution is complete) and is derived by extrapolating the *elimination phase* of the curve in Figure 33-9 to time = 0, which would have existed if distribution had been immediate and complete. A is an estimate, using the method of residuals, of the theoretical plasma concentration at time = 0 made immediately after intravenous injection of a bolus of drug. B is derived by extrapolation of the terminal slope line to time = 0. The method of residuals merely corrects the

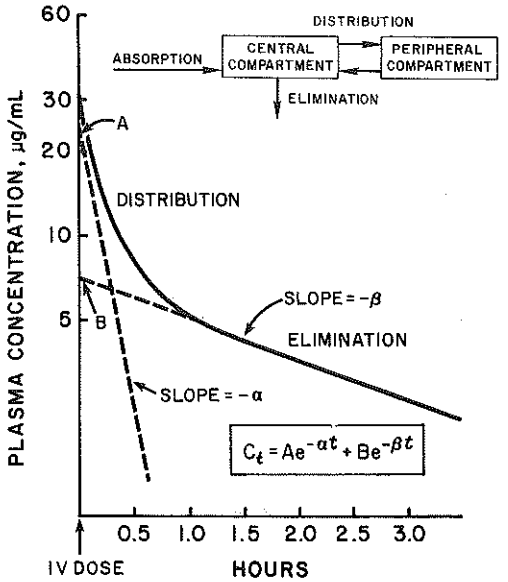

Figure 33-9 Decline of plasma concentration versus time after intravenous administration of a drug best characterized by a two-compartment model.

measured plasma level for the amount of drug distributed into tissue (as estimated on the extrapolated slope).

For simplicity, the intravenous bolus one-compartment model is used for illustrative purposes. After introduction of an intravenous bolus dose (D_0) into the single compartment, the drug is assumed to distribute instantaneously through all fluids and tissues of the body. The property of kinetic homogeneity is also assumed.

In TDM, it is preferable to work with concentrations of a drug in this homogeneous compartment, so D_1 (amount of drug in the compartment) is divided by a volume term. This volume term is called apparent *volume of distribution,* or V_d. It is not a real volume in the physiological sense, but instead is a proportionality constant to translate the absolute amount of drug present in the compartment into its concentration relative to a volume.

The V_d can be determined easily for the one-compartment model. When $t = 0$ (the time the drug bolus is introduced), D_0, the amount of drug given and corrected for bioavailability (f), is equal to the amount of drug in the compartment; the blood concentration (C_0) is

$$C_0 = \frac{D_0 \times f}{V_d} \tag{3}$$

Reorganization of this relationship provides the mathematical description of volume of distribution

$$V_d = \frac{D_0 \times f}{C_0} \tag{4}$$

The units of V_d are usually liters (L) or liters per kilogram of body weight (L/kg). Although V_d is a mathematical term and not a real physiological parameter, it is useful for contrasting degrees to which different types of drugs distribute. For instance, the polar hydrophilic drug gentamicin has a $V_d = 0.2$ L/kg, whereas the nonpolar lipophilic drug digoxin has a $V_d = 10$ L/kg. Gentamicin is concentrated in the blood, whereas digoxin is predominantly distributed into tissue.

Using the same assumptions, the first-order elimination rate constant can be determined. Referring to Figure 33-8, note that the relation between C_t and time is a natural logarithmic function where

$$\ln C_t = \ln C_0 - kt \tag{5}$$

Given a zero time blood drug concentration (C_0), a nonzero time concentration (C_t), and a defined time (t), then k can be readily determined either algebraically, graphically, or with appropriate software. For example, in a graphical plot of ln C_t versus t, the slope of the linear relationship is $-k$. The elimination rate constant k represents the fraction of drug removed per unit of time and has units of reciprocal time (min^{-1}, h^{-1}, day^{-1}). The overall elimination rate constant (k) includes the renal constant (k_{CR}), the biliary constant (k_{CB}), the metabolic constant (k_{CM}), and others such that $k = k_{CR} + k_{CB} + k_{CM}$.

The elimination rate constant (k) can be related to another parameter, half-life (τ), by the following equation:

$$\tau_{1/2} = \frac{0.693}{k} \tag{6}$$

Half-life (τ) is usually defined as the time required for the amount of drug in blood to decline to one half of a measured value. Figure 33-8 demonstrates how the half-life can be rapidly determined from a semilog plot of drug concentration versus time. Two or more successive concentrations collected at times t_1 and t_2 are required for the estimate of k used in the calculation of half-life

$$k = \frac{\ln C_{t_1} - \ln C_{t_2}}{t_2 - t_1} \tag{7}$$

If the measured half-life differs markedly from reported values for the drug in question, a component of elimination is likely to be the cause (i.e., decreased k_{CR} in renal impairment or decreased k_{CB} or k_{CM} in liver dysfunction).

Total body clearance (Cl_T) is defined as the theoretical total volume of blood, serum, or plasma completely cleared of drug per unit of time. It is usually expressed in units of mL/min, L/hr, mL/min/kg, or L/hr/kg. Like the elimination rate constant, Cl_T is the sum total of all the clearances contributed by each elimination route (i.e., $Cl_T = Cl_{CR} + Cl_{CB} + Cl_{CM} + \ldots$). Clearance is a most important parameter, because it provides a better representation than does k of the body's ability to eliminate a drug. In addition, Cl_T has more physiological meaning and is readily used to relate the dosing rate to steady-state concentration.

Clearance is mathematically related to V_d and k as

$$Cl_T = V_d k \tag{8}$$

Actual calculation of clearance is made using the pharmacokinetic approach of deriving the *a*rea *u*nder the *c*urve (AUC) from the time versus concentration curves shown in Figures 33-8 and 33-9. Clearance is described by

$$Cl_T = \frac{D_0 \times f}{\text{AUC}} \tag{9}$$

where AUC is the *a*rea *u*nder the *c*urve described by the plasma concentration versus the time histogram and integrated over time from zero to infinity.

In TDM, we are rarely concerned with a drug administered as a single, one-time intravenous bolus. Drugs administered repetitively pose the usual therapeutic situations. Figure 33-3 shows that a drug repetitively administered at a fixed dosing interval will accumulate in the body until a steady-state condition exists. Note that the normal dosing cycle is once each half-life (τ). *Steady state* is defined as that point in the dosing scheme when the amount entering the circulation (governed by the dosing rate) equals the amount eliminated (governed by the elimination rate).

Assuming first-order elimination, five to seven half-lives of a drug are required to reach 97% to 99% of a steady-state value. At steady state, assuming τ is constant, the profiles of concentration versus time should be superimposable from dose to dose.

Steady-state drug concentration (C_{ss}) at any time during a dosing interval is described by equation (10)

$$C_{ss} = \frac{(D_0 \times f)e^{-kt}}{V_d(1 - e^{-kt})} \tag{10}$$

In TDM, the maximum ($C_{max\text{-}ss}$) and minimum ($C_{min\text{-}ss}$) steady-state concentrations are often of primary interest (see Figure 33-3). Hence, the following equations are more useful:

$$C_{max\,SS} = \frac{D_0 \times f}{V_d(1 - e^{-kt})} \tag{11}$$

$$C_{min\,SS} = \frac{(D_0 \times f)e^{-kt}}{V_d(1 - e^{-kt})} \tag{12}$$

Again, recall that equations (10) through (12) apply only to dosing by repeated intravenous bolus. They are useful only when D_0, f, V_d, k, τ, and t (dosing intervals) are known.

Model-Independent Relationships

Model-independent relationships are frequently used in evaluation of clinical pharmacokinetics, because there are fewer relationships to remember, fewer restrictive assumptions, a more general insight into elimination mechanisms, and easier computations. However, model-independent relationships are not without their disadvantages; conceptualization of compartments or physiological spaces may be lost, specific information that may be clinically relevant or pertinent to mechanisms of distribution or elimination can be lost, and the difficulty can be increased in constructing profiles of concentration versus time.

The most frequently used model-independent approach applies the concept of median blood concentration, C (see Figure 33-3) and is described by

$$C = \frac{D_0 \times f}{Cl_T \times \tau} \tag{13}$$

This equation may be used for any drug. The equation is most useful when the half-life of a drug is much greater than t, the dosing interval.

Drug Disposition

Many factors have a profound influence on the pharmacokinetics of drugs and consequently on a patient's pharmacological response (Box 33-1). For example, the consideration of the patient's history, with particular emphasis on their pathophysiological state and adjunct drug therapy, is essential at the initiation of drug therapy and TDM. Other important factors include how a drug is absorbed, distributed, metabolized, cleared by the liver, biotransformed, and excreted.

Absorption

Most drugs administered continually to patients over a long period of time are administered extravascularly. Although intramuscular and subcutaneous routes are used, the oral route accounts for administration of most of the extravascular doses. The absorption process depends on the drug dissociating from its dosing form, dissolving in gastrointestinal fluids, and then diffusing across biological membrane barriers into the bloodstream. The rate and extent of drug absorption may vary considerably depending on the nature of the drug itself (e.g., solubility, pK_a), on the matrix in which it is present, and on the physiological environment (e.g., pH, gastrointestinal motility, vascularity).

The fraction of a drug that is absorbed into the systemic circulation is referred to as its *bioavailability*. The bioavailability (f) of a given drug is usually calculated by comparing, in the same subjects, the area under the plasma concentration-time curve (AUC) of an equivalent dose of the intravenous form and oral form

$$f = \frac{\text{AUC}_{oral}}{\text{AUC}_{iv}} \tag{14}$$

The bioavailability of a particular drug, if the drug is to be useful, must be great enough so that the active component will pass in sufficient amount and in a desirable time from the gut into the systemic circulation. Bioavailability is typically greater than 70% for drugs to be orally useful. An exception would be a case in which the lumen of the gastrointestinal tract is the site of drug action (e.g., antibiotics used to sterilize the gut). Low bioavailability would then be considered advantageous.

Some drugs that are rapidly and completely absorbed nevertheless have low bioavailability to the systemic circula-

BOX 33-1 Factors That Influence Drug Disposition in Humans

Demographic Factors
- Age category (premature infant, neonate, infant, prepubescent and postpubescent child, adult, elderly adult)
- Weight
- Gender
- Race
- Genetic constitution

Disease-Related Factors
- Liver disease (cirrhosis, hepatitis, cholestasis)
- Kidney disease
- Thyroid disorders (hypothyroidism or hyperthyroidism)
- Cardiovascular disease (arrhythmias, congestive heart failure)
- Gastrointestinal disease or disorder (sprue or other malabsorption syndromes, peptic ulcer, colitis)
- Cancer
- Surgery
- Burns
- Nutritional status (cachectic or anorexic states)

Extracorporeal Factors
- Hemodialysis
- Peritoneal dialysis
- Cardiopulmonary bypass
- Hypothermia or hyperthermia

Chemical and Environmental Factors Influencing:

Absorption of Drug
- Food or co-administered drug affecting extent and rate of absorption

Distribution of Drug
- Co-administered drug affecting binding to plasma proteins or tissue receptors

Metabolism of Drug
- Food intake (carbohydrates, proteins, lipids) competing for metabolizing systems
- Co-administration of drug that induces metabolizing enzymes (e.g., phenobarbital)
- Co-administration of drug that inhibits metabolizing enzymes (e.g., cimetidine)

Excretion of Drug
- Co-administration of drug that competes for renal tubular secretory paths (e.g., probenecid or penicillin)
- Changes in urinary flow rate
- Co-administration of compounds that enhance tubular reabsorption (e.g., sodium bicarbonate or phenobarbital)

tion. This is true of drugs with a high *hepatic extraction rate.* After oral administration, drugs that are absorbed in the lumen of the small intestine are carried by the portal vein directly to the liver. A drug with a high hepatic extraction rate may be extensively metabolized by the liver before it reaches the systemic circulation. This phenomenon is called the *first-pass effect.*

In addition to the extent of absorption, the rate of absorption is important. The absorption of a drug is generally considered a first-order process, and the absorption rate constant of a drug is usually much greater than its elimination rate constant. By manipulating their formulations (e.g., theophylline, quinidine) to produce "slow-" or sustained-release products, the apparent rate of absorption of many drugs can be controlled. For example, formulations that provide sustained release permit drugs taken orally to be taken at less frequent intervals. Conditions that may influence the extent or rate of drug absorption include abnormal gastrointestinal motility; diseases of the stomach, and the small and large intestine; gastrointestinal infections; radiation; food; and interaction with other substances in the gastrointestinal tract. One should be particularly aware of co-administered drugs that directly affect gut absorption, such as antacids, kaolin, sucralfate, cholestyramine, and antiulcer medications, and co-administration of morphine, which slows gut motility.

Distribution

After a drug enters the vascular compartment, it interacts with various blood constituents and is carried by various transport processes to different body organs and tissues. The overall process is referred to as *distribution.* The factors determining the distribution pattern of a drug are: (1) binding of the drug to circulating blood components, (2) binding to fixed receptors, (3) passage of the drug through membrane barriers, and (4) the ability to dissolve in structural or storage lipids. Molecular weight, pK_a, lipid solubility, and other physical and chemical properties of the drug also are important determinants of distribution.

Once a drug enters the systemic circulation, it distributes and comes to equilibrium with many of the blood components. One of these clinically significant groups is plasma proteins. An equilibrium exists between a *free* and protein-*bound* drug. It is generally believed that only the free fraction of the drug is available for distribution and elimination. In addition, only the free drug is available to cross cellular membranes or to interact with the drug receptor to elicit a biological response. Therefore changes in the protein-binding characteristics of a drug can have a profound influence on the distribution and elimination of a drug and on the manner in which steady-state concentrations are interpreted. Each drug has its own characteristic protein-binding pattern that depends on its physical and chemical properties. As a general rule, however, acidic drugs are bound primarily to albumin, and basic drugs primarily to globulins, particularly α_1-acid glycoprotein (AAG). Some drugs bind to both albumin and globulins.

Depending on its affinity for plasma proteins, a drug may be either tightly or loosely bound. A weakly bound drug can be displaced from its protein sites by a drug with a greater affinity for the plasma protein-binding sites. For example,

phenytoin and valproic acid, drugs that are frequently coadministered for epilepsy, compete with each other as they bind to albumin. Because valproic acid is present at higher concentration, its mass causes a significant shift of phenytoin from bound to free form. Protein binding of a drug also depends on the physical characteristics of the plasma proteins and on the presence or absence of fatty acids or other drugs in the blood. Fatty acids can displace a drug from its protein-binding sites; tightly bound drugs are not displaced, but a weakly bound drug can be displaced quite rapidly by free fatty acids present in increased concentrations. It is important to recognize that even though the total drug concentration may remain unchanged, displacement of a drug from its plasma protein-binding sites elevates free drug concentrations and can result in clinical toxicity.

Anything that alters the concentration of free drug in the plasma ultimately alters the amount of drug available to enter tissue and interact with specific receptor systems. Disease states can alter free drug concentrations. For example, the composition of plasma is altered by an increase in nonprotein nitrogen compounds in uremia, by acid-base and electrolyte imbalances, and often by a decrease in albumin; free drug concentrations are frequently elevated. Patients may experience adverse effects that are a direct consequence of the increased free drug concentrations. If one monitors total plasma drug concentration in these patients, little change might be noted because the total concentration remains unchanged, or may even decrease, while the free fraction may increase significantly. Marked alterations of free drug concentration are not detected because the total drug concentration may not be dramatically different from that observed in healthy patients. For example, phenytoin is 90% bound and 10% free in healthy subjects. In uremic patients, 20% to 30% of the total plasma concentration of phenytoin may be free. If one considers a healthy patient who has a total plasma phenytoin concentration of 15 μg/mL, the free phenytoin concentration is likely to be 1.5 μg/mL. If a uremic patient has a total concentration of 15 μg/mL, the free drug concentration may be 4.5 μg/mL. A free phenytoin concentration of 4.5 μg/mL is sufficient to precipitate severe phenytoin side effects, including lethargy and increased seizure frequency. Therefore, in uremic patients, it is advisable to quantify free phenytoin concentrations and adjust the drug dose to maintain free phenytoin concentration at approximately 2.0 μg/mL.

Alteration of protein concentration in response to acute stress can alter free drug concentration. For example, after myocardial infarction, there is a rapid rise in AAG concentration. Lidocaine is used to control arrhythmias because of the infarction, but lidocaine is a basic drug that is highly bound to AAG. Doses of lidocaine adequate to control arrhythmia immediately after infarction are likely to become ineffective 48 to 72 hours later because the higher concentration of AAG that occurs after infarction diminishes the amount of free drug available to tissue. The arrhythmia reappears and because the total lidocaine plasma concentration necessary to control the arrhythmia seems to be in the toxic range, the lidocaine dose is decreased when in reality it should be increased to maintain the optimal free concentration.

Some drugs exhibit saturation of the available plasma protein-binding sites at optimal total drug concentrations. For example, disopyramide binding is concentration dependent and varies widely from patient to patient. Consequently, its total concentration and the observed clinical responses vary markedly from patient to patient. Valproic acid is also a drug that shows saturation at concentrations greater than 100 μg/mL. Thus, an increase of total plasma valproic acid concentration from 100 to 125 μg/mL represents a significant increase in the free valproic concentration.

Any change in normal physiological status can alter free drug concentrations and thus change the distribution of drugs between plasma and tissue. Geriatric patients often exhibit hypoalbuminemia with a notable decrease in protein-binding sites for drugs. In the elderly, the classical signs of drug intoxication are not usually apparent; instead, the clinical symptoms of drug intoxication are manifested as impaired cognitive function—particularly confusion. Elderly patients may be considered senile when in reality an increased free drug concentration is affecting their cognitive ability. Reduction of drug dose to decrease the free drug concentrations may result in dramatic improvements in these patients' personalities.

Estimation of the free drug concentration will continue to be of interest to TDM. Ultrafiltration techniques are useful in satisfying this need. However, it should be remembered that laboratory measurements now only *estimate* the free drug concentration in circulating blood. Artifacts introduced in drawing, processing, and storing blood can modify dissociation equilibria for some drugs. Despite these drawbacks, free drug estimations by ultrafiltration are superior to estimations of free drug concentration based on measurements in saliva. Few drugs show a strong correlation between salivary concentration and free drug concentration in plasma. In addition, collection of saliva from acutely ill patients is difficult.

Metabolism

The rate of the enzymatic process to metabolize a drug can be estimated using the Michaelis-Menten equation

$$\frac{dC}{dt} = \frac{V_{max} \times C}{K_m \times C} \tag{15}$$

where V_{max} is the maximum velocity of the reaction; K_m, the Michaelis-Menten constant is the drug concentration at which the rate of metabolism is one half of the maximum; and C is the blood drug concentration.

Drugs are usually administered to achieve concentrations in the blood considerably below the K_m of a particular drug. Therefore if K_m is much greater than C, equation (15) can be simplified to

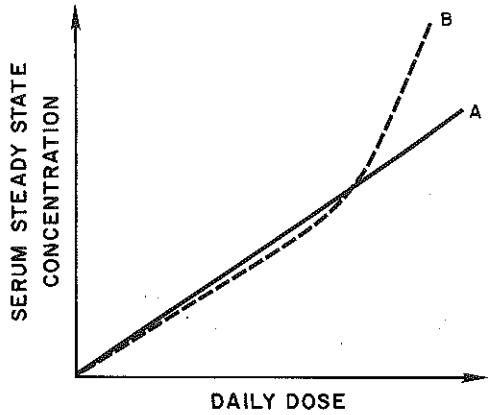

Figure 33-10 Dose-response curves. *Line A* illustrates the linear relationship between serum drug concentration and total daily dose of a drug that displays first-order kinetics typical of most drugs. *Line B* illustrates the dose-response relationship for a drug that displays capacity-limited kinetics because of a saturable enzyme or transport mechanism; in this situation, serum concentration becomes independent of total daily dose, and the relationship of drug concentration to dose becomes nonlinear. *(Modified from Pippenger CE. Practical pharmacokinetic applications. Syva Monitor, San Jose:Syva Co, January, 1979:1-4.)*

$$\frac{dC}{dt} = \frac{V_{max} \times C}{K_m} \tag{16}$$

and V_{max}/K_m can be written as the constant, k, such that

$$\frac{dC}{dt} = kC \tag{17}$$

where k is a simple first-order rate constant for the metabolic elimination. In other words, the rate of metabolism is proportional to the concentration of a drug. *First-order kinetics* are characteristic of the metabolism of most drugs.

In the event that the rate of metabolism approaches V_{max}, the rate becomes independent of concentration and thus descriptive of a *zero-order* process. Several drugs, notably phenytoin, salicylate, ethanol, and theophylline, cannot be characterized by simple first-order kinetics. Instead, the rate of metabolism of these compounds is said to be *capacity-limited* or *nonlinear,* meaning clearance or the apparent half-life changes with changes in concentration. Figure 33-10 (curve *B*) shows how a dose-response curve may be linear (first order) until the capacity of some pathway is reached; it then becomes nonlinear. Equations (10) and (13) have shown the relationship between plasma concentration, total body clearance, half-life, and dose. Therefore, important clinical considerations arise when a patient is treated with a drug that displays nonlinear kinetics. First, changes in dosing result in disproportionate changes in steady-state drug concentrations so that titration to appropriate serum levels must be approached conservatively. Secondly, because both clearance and apparent half-life of the drug change with increasing drug concentration, the length of time required to reach a new steady-state concentration is prolonged.

All of the equations previously described for predicting dose or concentration assume linear kinetic systems; they are therefore not adaptable to treatment with drugs that display nonlinear kinetics. Using a linearized Michaelis-Menten equation, methods for predicting phenytoin dose and concentration have been developed and applied to individual drug dosing regimens.

Hepatic Clearance

For those drugs dependent solely on hepatic elimination, total body clearance (Cl_T) equals hepatic clearance (Cl_H). When the liver is considered from a purely physiological perspective, the hepatic clearance is determined by the hepatic blood flow (Q) and the hepatic extraction fraction (E).

$$Cl_H = Q \times E \tag{18}$$

The hepatic extraction fraction of a drug reflects the affinity of a particular drug for hepatic microsomal enzymes; E can be found experimentally or calculated by the following equation:

$$E = \frac{C_a - C_e}{C_a} \tag{19}$$

where C_a is the concentration of the drug in blood entering the liver, and C_e is the concentration of the drug in the hepatic venous effluent. For drugs that possess a high extraction fraction, hepatic clearance approaches hepatic blood flow (Q). The total body clearance of highly extracted drugs primarily depends on hepatic blood flow for their elimination. These drugs usually have low bioavailability because of the first-pass effect described earlier. Lidocaine is an example of such a drug. The clearance of low-extracted drugs is less dependent on blood flow and more dependent on the quantity and quality of the hepatic microsomal enzymes. Total body clearance of these drugs is affected by hepatic function, enzyme inducers and inhibitors, and changes in free drug concentration. A review on this subject is available.[119]

Biotransformation

The liver is the principal organ responsible for xenobiotic metabolism. One of its major roles is to convert lipophilic nonpolar molecules to more polar water-soluble forms. The drug molecule (a xenobiotic) can be modified by phase I reactions, which alter chemical structure by oxidation, reduction, or hydrolysis; or by phase II reactions, which conjugate the drug (glucuronidation or sulfation) to create more water-soluble forms. Typically, both phase I and phase II reactions occur. Most drug metabolism takes place in the microsomal fraction of the hepatocytes, where many environmental chemicals and endogenous biochemicals (xenobiotics) are also processed by the same mechanisms.

Enzymes of the hepatic microsomal system can be induced or inhibited. Enzyme induction and inhibition have greatest significance for drugs with low to moderate hepatic extraction fractions.

Microsomal enzyme induction leads to an increase in the activity of enzymes present, most commonly through increases in the mass quantity of the oxidizing enzymes. The many isoenzymes of cytochrome P_{450} are affected variably by different enzyme-inducing drugs. For example, phenobarbital and theophylline and polycyclic hydrocarbons induce enzyme activity differently. Two classical and clinically relevant enzyme inducers can be contrasted.

Phenobarbital Induction

Phenobarbital represents the type of enzyme inducer with broad induction effects. After a latency period, production of cytochrome P_{450}, cytochrome P_{450} reductase, and related enzymes is increased. In addition, liver weight, hepatic blood flow, bile flow, and production of hepatic proteins also all increase. This induction apparently increases the P_{450} isoenzyme mass for which debrisoquin is a substrate, because the hepatic clearance of debrisoquin is increased after phenobarbital administration. This enzyme is referred to as cytochrome P_{450}-2D6 (Cyp 2D6). Phenobarbital induction has little effect on theophylline clearance, suggesting a different isoenzyme for theophylline metabolism.

Theophylline and Polycyclic Hydrocarbons Induction

Theophylline and polycyclic hydrocarbons in tobacco smoke (3-methylcholanthrene) represent a second type of enzyme inducer with broad induction effects. They induce CyP 1A in which no change in P_{450} reductase occurs and a different terminal oxidase appears. After this type of induction, the clearance of theophylline but not that of antipyrine is increased. These substances have served as prototypes for the classification of enzyme inducers. Obviously, when patients are on a drug with a narrow therapeutic index, their dosing regimen would need to be adjusted should a known enzyme-inducing drug be added to or deleted from their therapy.

Because the drug-metabolizing enzymes of the liver and gastrointestinal tract are nonspecific and interact with a wide variety of endogenous and exogenous substances, it is not surprising that the presence of one drug inhibits the metabolism of a second drug that is co-administered. Several general mechanisms have been proposed to describe these events. They include substrate competition, competitive or noncompetitive inhibition, product inhibition, and repression (where the amount of enzyme is reduced by either decreased synthesis or increased degradation). Most drug-drug interactions probably fall into the categories of substrate competition or competitive or noncompetitive inhibition. Examples of xenobiotics that have been shown to significantly inhibit drug metabolism include antiretrovirals, cimetidine, erythromycin, fluconazole, grapefruit juice, and verapamil. As with enzyme inducers, the addition or deletion of an inhibitory drug in a patient's drug therapy requires appropriate TDM and dose adjustment of the affected drug. TDM allows one to monitor these processes and adjust dosing accordingly.

The role of TDM becomes particularly apparent for drugs that undergo hepatic or gastrointestinal metabolism. Wide variability in the rate of metabolism of any given drug exists not only in different patients in the general population but also in the same patient at different times and in different circumstances. This variability is due to factors such as age, weight, gender, genetics, exposure to environmental substances, diet, co-administered drugs, and disease. Furthermore, there is no acceptable, endogenous, biochemical marker by which hepatic or gastrointestinal function, and consequently hepatic or gastrointestinal capability for drug clearance, can be routinely assessed before drug therapy is initiated.

The biotransformation of drugs may produce metabolites that are pharmacologically active. In such instances, the metabolite should also be measured because it is contributing to the effect of the drug on the patient. Primidone and procainamide are examples of such drugs. If the metabolite is inactive, it need not be measured, but steps should be taken to ensure that it does not interfere in the analytical process.

Excretion

Excretion of drugs or chemicals from the body can occur through biliary, intestinal, pulmonary, or renal routes. Although each of these represents a possible mechanism of drug elimination, renal excretion is a major pathway for the elimination of most water-soluble drugs or metabolites and is important in TDM. Alterations in renal function may have a profound effect on the clearance and apparent half-life of the parent compound or its active metabolite(s); decreased renal function causes elevated serum drug concentrations and increases the pharmacological response.

Kidney function, in contrast to liver function, is readily and reliably evaluated by estimation of creatinine clearance (see Chapter 24). Creatinine is a metabolic product of muscle metabolism and is produced at a constant rate by the body. It is primarily eliminated from the body by the kidneys through the glomerular filtration mechanism. Renal clearance of creatinine at 120 mL/min approximates the glomerular filtration rate of 90 to 130 mL/min. Therefore measurement of creatinine clearance on a routine basis provides an effective tool to evaluate kidney function. A strong correlation has been shown to exist between creatinine clearance and the total body clearance or elimination rate constant of those drugs primarily dependent on the kidneys for their elimination. Examples of drugs whose therapeutic use is adjusted to account for changes in creatinine clearance include amikacin, digoxin, gentamicin, tobramycin, and vancomycin.

Clinical Utility

TDM is most valuable when the drug in question is used chronically and has a narrow therapeutic index. A number of advantages can be realized by a TDM program.

1. Noncompliance can be recognized. Many patients, especially those with chronic disease, require prolonged drug therapy. The problem of compliance is particularly evident with patients who are characteristically free of pain or in unusual discomfort as with epilepsy, asthma, hypertension, mild heart disease, and transplantation. Patients may develop a sense that their disease has been cured and they no longer need the drug. The end results of noncompliance are exacerbation of the existing disorder and treatment failure. Greenstein reported in 1998 the results of a large, multicenter study that estimated 23% noncompliance with chronic therapy for a life-threatening disorder.[46] Shemesh has reported that the best means to document noncompliance is the assessment of blood concentration.[127] Drug concentration values provide positive feedback to physicians regarding patient compliance, allowing for identification of the noncomplying patient.
2. Patients undergoing changes in drug disposition characteristics can be recognized. Occasionally, the disposition pattern of drugs in particular individuals may change from the average patient population parameters. Aberrant disposition may be attributable to an effect of a drug or disease state not previously recognized. The clinical condition and individual metabolism of patients may not only differ from one to another but may change in the same patient during treatment. Both the pharmacokinetic disposition and the pharmacodynamic response to a given drug dose in individual patients may vary widely as a direct consequence of genetic influences. Studies of these genetic factors (pharmacogenetics) have clearly demonstrated that all aspects of pharmacokinetics and pharmacodynamics are under genetic control. One of the frequent examples of such a change can be seen when adolescents progress through puberty—most drug disposition parameters change, requiring frequent dose and dosing interval adjustment, guided by TDM.
3. Therapeutic drug regimens can be adjusted during periods of continuous physiological change. Normal alterations in physiological state, as in pregnancy or aging, or continuous pathophysiological or hemodynamic changes as consequences of disease, surgical treatment of disease, and the healing process complicate assessment of drug dose needs.
4. Baseline concentrations associated with an optimal therapeutic regimen can be identified. After a patient has undergone an extensive workup to define an appropriate therapeutic regimen, a physician can establish a baseline drug concentration at which the patient responds well. Should the patient's response change significantly in the future, the physician can rapidly document whether the patient has been compliant or whether a new disease state may be altering the pharmacodynamics or pharmacokinetics of a drug.
5. The most appropriate drug-dosing regimens can be initiated and maintained for a particular patient.

ANALYTICAL CONSIDERATIONS

The evolution of TDM has been facilitated by the development of rapid, sensitive, and specific analytical techniques. These technical advances have driven the growth of the fields of pharmacology, biopharmaceutics, and pharmacokinetics.

Analytical Techniques

Analytical techniques that are used to measure therapeutic drugs includes immunoassay and instrumental techniques, such as chromatographic and electrophoretic procedures, and the so-called "hyphenated techniques," where chromatographs are coupled with a mass spectrometer.*

Immunoassay

Radioimmunoassay (RIA) techniques permit quantification of drug concentration in microliter volumes of serum at nanograms per milliliter concentrations. However, the complexity of this technique, long turnaround time, problems, with waste disposal, and lack of RIA for a wide variety of drugs have prevented its widespread adoption for routine drug assays. Few RIAs now are used for TDM.

Proliferation of TDM to all laboratories and physicians was achieved with the development of the nonisotopic immunoassay (see Chapter 9). Numerous systems have evolved to provide this technology in both the clinical laboratory and physician's office. The major advantages of these systems are their microcapability, specificity, rapidity, ease of performance, and adaptation to automated analyzers (see Chapter 11).

Instrumental Methods

Gas-liquid chromatography (GLC) permits separation of parent drug from metabolite(s) and differentiation from co-administered drugs and endogenous compounds. It has the ability to separate and quantify several drugs within a given class of drugs.[122] Disadvantages of GLC include the need for (1) a relatively large volume of sample to achieve biologically important sensitivity and (2) chemical derivatization to ensure that the analytes have the prerequisite volatility. Advances in the development of mass spectrometer detectors (GC/MS) and application of capillary columns have increased the sensitivity of the instruments to such an extent that drug analysis can now be routinely performed on microliter (μL) volumes of sample.

High-performance liquid chromatography (HPLC) techniques offer versatility with minimal sample preparation. Its specificity and sensitivity, relatively small sample requirements, and the ease of operation make HPLC a practical alternative to GLC. HPLC has also been adapted to the simultaneous quantification of a large variety of drugs and

*Several analytical methods and case studies for therapeutic drugs are found on this book's accompanying Evolve site, found at http://evolve.elsevier.com/Tietz/textbook/.

their metabolites (see Chapter 6 and a review by Sadeg and colleagues[120] for a discussion of chromatographic techniques). Capillary electrophoresis, a relatively new technique (see Chapter 5), has been used to measure a variety of drugs,[104,137] including caffeine,[118] various cardiac drugs,[99] felbamate,[128] and gabapentin.[41]

The combination of HPLC with tandem mass spectrometers (LC/MS/MS) has revolutionized the analytical approach to TDM. This technology allows for direct analysis of biological specimens with minimal sample preparation, high sensitivity, specificity, precision, and high throughput.

Issues of Concern

Analytical issues of continuing concern for a TDM service include the following:

1. Assay methods used for TDM should be accurate and reproducible. All clinical laboratories with a TDM service should be actively involved in an internal quality control and external proficiency testing program. In addition, sample volume and assay turnaround time should be considered in selecting the most appropriate analytical method.
2. Each laboratory should inform the medical staff about therapeutic and toxic concentration ranges, analytical method (when appropriate), action values, required sample volume, and collection tube specifications.
3. Guidelines should be available for ideal sample schedules for each individual drug monitored. Steady-state trough concentrations usually are most desirable; however, other sample schedules may be appropriate, depending on the properties of the drug or the individual needs of the patient.
4. The time and date of collection of the drug sample and of the last dose should be noted. To assess steady-state conditions, the length of time a patient has been on a particular regimen should be known. In vitro conditions affecting stability of the drug in a sample (e.g., penicillin or heparin and aminoglycoside antibiotics) or the assay specificity (e.g., presence of hemolysis) should be considered for sample handling procedures.
5. Because laboratory reports become part of a patient's chart, it is useful to devise a reporting format that incorporates all of the data necessary for interpretation (drug formulation, frequency and amount, plasma concentration, time of dose, time of draw, and other drugs coadministered).

SPECIFIC DRUG GROUPS

Drugs that are routinely monitored are conveniently classified by the kind of therapy they support (e.g., antibiotics, control of epilepsy, management of respiratory or cardiac function, suppression of immune response). An analytical method for one drug in a grouping is often applicable to other drugs in the same grouping. The following discussion is organized in accordance with classifications commonly recognized. Note that some drugs, such as salicylate and nitroprusside (assessed by the quantification of thiocyanate), are discussed in Chapter 34.

Antiepileptic Drugs

Many antiepileptic drugs are used to treat seizures (Table 33-1). Most are analyzed collectively by either GLC or HPLC[68] or individually analyzed by immunoassay. The advantage of HPLC or GLC is that simultaneous analyses can be accomplished. Immunoassay procedures are less labor intensive and are usually quicker than HPLC or GLC for a single analyte; however, analysis of multiple antiepileptics or metabolites requires additional assays. For example, GLC[38] and HPLC[43] methods allow for the simultaneous measure of several common anticonvulsants. Immunoassay, however, is the mainstay of monitoring these drugs in most clinical laboratories.

Carbamazepine

Carbamazepine, proprietary name *Tegretol,* is used in the treatment of generalized tonic-clonic, partial, and partial-complex seizures. It is also used for the treatment of pain associated with trigeminal neuralgia. Like phenytoin, carbamazepine modulates the synaptic sodium channel, which prolongs inactivation, reducing the ability of the neuron to respond at high frequency.[51] The physiological effect of this action is reduction in central synaptic transmission, aiding in control of abnormal neuronal excitability. Carbamazepine also has an antidiuretic effect, reducing concentrations of antidiuretic hormone.

After oral administration, carbamazepine is slowly but erratically absorbed with wide individual variability. Over 80% of the drug is protein bound.. The elimination half-life early in therapy is approximately 24 hours. With chronic therapy, the enzyme cytochrome P_{450} 3A4 (CyP 3A4) and its associated drug transporter P-glycoprotein (Pg)—responsible for metabolism—are induced, and the elimination half-life is reduced to 15 to 20 hours. Because hepatic metabolism is the principal means by which plasma concentration is reduced, any reduction in liver function results in drug accumulation.

The therapeutic concentration range for optimal pharmacological effect of carbamazepine is 4 to 12 μg/mL. Toxicity associated with excessive carbamazepine ingestion occurs at plasma concentrations in excess of 15 μg/mL and is characterized by symptoms of blurred vision, paresthesia, nystagmus, ataxia, drowsiness, and diplopia. Side effects unrelated to plasma concentration include development of an urticarial rash, which usually disappears on discontinuation of the drug, and hematological depression (leukopenia, thrombocytopenia, and aplastic anemia).

The active metabolite of carbamazepine is carbamazepine-10,11-epoxide formed by action of CyP 3A4. This metabolite has been found to accumulate in children to concentrations equivalent to carbamazepine. It may contribute to symptoms of intoxication in children who have a thera-

TABLE 33-1 Pharmacokinetic Parameters of Antiepileptic Drugs

Drug	Minimum Effective Concentration (MEC) (μg/mL)	Minimum Toxic Concentration (MTC) (μg/mL)	Average Half-Life (hr)	Average Volume of Distribution (L/kg)	Average Oral Bioavailability (%)	Average Protein Binding (%)	Important Metabolizing Enzymes
Carbamazepine	4	12	15-20	1.4	70	75	CyP 3A4, Pg
Carbamazepine-10,11-epoxide	0.4	4	7	NA	NA	50	CyP 2C19

Zonisamide	10	30	50-70	1.4	50	50	CyP 2C19

NA, Not applicable.

peutic plasma concentration of the parent drug. Because carbamazepine is metabolized by CyP 3A4, drugs that induce this enzyme (erythromycin, oxcarbazepine, phenytoin, and St. John's Wort) increase the rate of clearance of carbamazepine.

Co-administration of erythromycin, phenytoin, or valproic acid increases the rate of metabolism of carbamazepine, reducing the blood concentration. Itraconazole and grapefruit juice interfere with CyP 3A4, increasing carbamazepine levels.

Because of carbamazepine's relatively long half-life, the specimen yielding the most useful information is the one representing the trough concentration, although in the case of suspected mild intoxication, the peak value of the plasma concentration correlates more closely with toxicity. The peak specimen should be collected 4 to 8 hours after the oral dose.

Ethosuximide

Ethosuximide, proprietary name *Zarontin,* is used for the treatment of absence seizures characterized by brief loss of consciousness. Ethosuximide reduces the flow of calcium through T-type calcium channels in the synapse of thalamic neurons; because thalamic neurons are the main source of 3-Hz spike-wave rhythms in absence seizures, reduction of calcium flow slows the rate of these seizure-inducing pulses.

Ethosuximide is readily absorbed from the gastrointestinal tract. In children its half-life is approximately 33 hours, although this may be prolonged in adults. The drug is cleared mainly by metabolism as the hydroxyethyl metabolite and the glucuronide ester (metabolized by UDP-glucuronosyltransferase–UGT, or sulfate ester metabolized by sulfotransferase—ST) of the hydroxyethyl metabolite; the exact cytochrome enzyme isomer has not been identified. The trough specimen yields the most useful information regarding therapeutic efficacy. The optimal therapeutic concentration of ethosuximide is 40 to 100 μg/mL. Toxicity related to an excessive blood concentration of ethosuximide is rare. Symptoms of gastrointestinal distress, lethargy, dizziness, and euphoria may be encountered early in therapy, but patients usually become tolerant to these symptoms.

Levetiracetam

Levetiracetam *(Keppra)* is approved for adjunctive therapy and treatment of partial onset seizures in adults with epilepsy. Levetiracetam is 100% bioavailable. Once absorbed, it is <10% bound to protein and has a volume of distribution of 1.0 L/kg. Following an oral dose, it reaches maximum

concentration in 1 hour. The clearance half-life is 7 ± 1 hour and clearance is 0.96 mL/min/kg predominantly by renal elimination of the parent drug. Twenty-four percent of the parent drug undergoes hepatic metabolism by CyP 2C19 to an inactive carboxylic acid metabolite. Levetiracetam is cleared predominantly by renal function. A 40% reduction in levetiracetam clearance is expected is expected if the creatinine clearance is <30 mL/min. Prepubescent children clear levetiracetam 40% faster than adults. There are no pharmacokinetic interactions between levetiracetam and other antiepileptic drugs.
